Receptors. SEC binds to the perfused pancreas and the gastric mucosa of rats. in contrast to SEC bound to the pancreas, SEC bound to the gastric mucosa can be displaced by tetragastrin [1389].

Biological Effects. The activity of SEC is generally expressed in clinical units (CU) which are determined in the dog (pancreatic secretion of aqueous nahCO_3): 1 mg of SEC has 4000 – 5000 CU. The physiological level of about 20 pg/mL, observed in the human jejunum after H^+ stimulus, should be achieved after an infusion of 0.03 CU kg^{-1} h^{-1}.

SEC stimulates the release of an aqueous $NaHCO_3$-containing secretion from the panreas

which neutralizes any hydrochloric acid entering the small intestine [1390]. Cholecystokinin, neurotensin [1391], and adenosine [1392] potentiate the SEC-stimulated pancreatic secretion. SEC-induced protein secretion from the pancreas is described frequently but is due to impurities, such as cholecystokinin [1393].

Other effects of SEC include:

1) activation of adenylate cyclase and cAMP synthesis
2) proliferative effect in the pancreas which is potentiated by CCK [1394]
3) reduction of the plasma gastrin level and of the formation of gastric acid (via SRIH and prostaglandins [1395], potentiated by neurotensin [1391])
4) reduction of stress-induced hemorrhage from the stomach [1396]
5) vasodilative and motility inhibiting effect (dilation of the pancreatic ducts [1397], reduction of the lower esophageal sphincter pressure [1398], increase in the circulation to the pancreas and duodenum)
6) contraction of the pyloric sphincter (delay in the emptying of the stomach [1399])
7) potentiation of the CCK-stimulated flow of bile [1400]
8) release of insulin in vitro

Structure – Activity Relationships. Analogues of secretin that are more active than the native peptide have not been found. Shortening the molecule at the N- or the C-terminus produces less active products. For instance, SEC-(2 – 27)amide has only 1 % of the activity of secretin. The shortest known active sequence is SEC-(1 – 13): 0.1 mg/kg of this substance still exerts a significant effect on the pancreas. However, 1 mg/kg of SEC-(1 – 11)amide shows no activity in the rat. Similar to His^1, Asp^3, and Phe^6, Arg^{12} is important for secretin activity.

Secretin extended at the C-terminus by Gly-Lys-Arg (natural pro-SEC) still has about 80 % of the SEC activity [1401].

The Asp^3–Gly^4 bond of secretin is responsible for its frequently reported instability. In an acid medium the β-carboxyl group of aspartic acid acylates the adjacent C-terminal peptide bond. This aspartoyl peptide then rearranges to give a peptide in which the peptide bond is formed with the β-carboxyl group of aspartic acid (and not the α-carboxyl group). The Asp-Gly-(3 – 4) and the Asp-Ser-(15 – 16) bonds in p-SEC are cleaved in aqueous solution at pH 5 [1402]. The main decomposition product in neutral phosphate buffer is [β-Asp^3]SEC [1403]. In acidic acetate buffer (pH 4), SEC-(16 – 27), SEC-(4 – 27), [β-Asp^3]SEC, [3-aspartoyl]SEC, and [βAsp^{15}]SEC are formed [1403]. These decomposition products have little or no biological activity.

Uses. Secretin is generally administered parenterally, but the intranasal application of a dry powder has also been described. Secretin (Sekretolin, Hoechst) is applied parenterally in doses of 75 – 100 CU to test pancreatic function and to diagnose the Zollinger – Ellison syndrome. In contrast to healthy subjects, patients with the Zollinger – Ellison syndrome react to a diagnostic intravenous dose of secretin (75 CU) with increased plasma levels of gastrin and GIP and not a decreased level of gastrin [1402]. SEC normally increases the diameter of the pancreatic duct, but this is not the case in patients with chronic pancreatitis [1404]. Infusion of sekretolin (0.25 – 0.5 CU kg^{-1} h^{-1}) stops bleeding of the upper gastrointestinal tract [1405]. SEC improves the condition of patients suffering from peptic ulcers [1406]. The relaxing effect on the lower esophageal sphincter can be exploited in patients with achalasia [1398].

The insulin-releasing effect of SEC (2 CU/kg) can be used to differentiate between single insulinomas or nesidioblastosis and multiple B- cell adenomas or hyperplasia [1407].

7.2. Vasoactive Intestinal Peptide [1408]

Occurrence. Vasoactive intestinal peptide (VIP) [*37221-79-7*], M_r 3326, was first isolated along with secretin from the intestine of the pig. It is distributed throughout the body, primarily in the nervous system.

VIP is a peptide amide containing 28 amino acids. It is formed from the same prepropeptide as PHI-27 (pig) and PHM-27 (humans) that are peptide amides containing 27 amino acids. PHI-27 stands for peptide with N-terminal histidine and C-terminal isoleucinamide, PHM-27 for peptide with N-terminal histidine and C-terminal methioninamide. An extended version

of VIP with Gly-Lys-Arg at the C-terminus has also been found [1409].

p-,b-,r-,ca-,cu-,cap-,o-, and h-VIP are identical [1410]:

```
H S D A V F T D N Y T R L R K
Q M A V K K Y L N S I L Na
```

There is little difference in the sequences of h-PHM-27, p-, b- [1411], and r-PHI-27 [1412]; cu-PHI-27 is identical to p-PHI-27 [1413].

VIP and PHI-27 are found in the neurons of the central nervous system, in the digestive tract, lungs, urogenital tract, gallbladder [1414], exocrine glands, thyroid gland, adenohypophysis [1415], and the adrenal gland. It occurs associated with acetylcholine and galanine [1416].

Release. VIP is released by electrical stimulation of nerve fibers, from the gallbladder wall by stimulation of the vagus, and from the hypothalamus by prostaglandin E_1. Plasma levels are increased by oxytocin, sexual stimulation in women, the sucking stimulus [1417], physical stress [1418], operation stress [1419], and corticosterone [1420]. VIP is also released by Met-enkephalin and β-endorphin [1421] in the hypothalamus, by insulin in the intestine [1422], and by estrogen in the adenohypophysis [1423].

The release of VIP is inhibited by glucose infusions [1418], peripheral application of endogenous opiates [1418], pancreatic peptide, and somatostatin.

Patients with multiple sclerosis have a significantly lower level of VIP in their cerebrospinal fluid than healthy persons. Impotent men have a low plasma VIP level. In patients suffering from cystic fibrosis, fewer VIP-immunoreactive nerves are found in the eccrine sweat glands [1424]. Intravenous glucagon or secretin raises the plasma levels of gastrin and VIP in patients with Zollinger – Ellison syndrome [1425]. The treatment of patients with congestive heart failure with ACE inhibitors increases plasma VIP levels [1426].

Receptors [1427]. At least two high-affinity VIP receptors and one low-affinity VIP receptor may exist. The antagonist [4-Cl-D-Phe^6,Leu^{17}]VIP differentiates between two high-affinity VIP receptors in guinea pig acinar cells [1428]; carbachol binds to the low-affinity VIP receptors [1429]. The number of VIP receptors on human mononuclear leucocytes increases drastically in response to physical activity and an energy deficit [1430].

Biological Effects. In the cell, VIP stimulates the synthesis of cAMP and catecholamines (activation of tyrosine hydroxylase) [1431]. It also potentiates the muscarinic stimulation of the turnover of phosphoinositides [1432]. VIP inhibits the activation of the calmodulin-sensitive phosphodiesterase [1433]. VIP and acetylcholine act synergistically in secretion and circulation. PHI exhibits VIP-like activity. VIP has many biological effects [1408]. The most important are listed below:

1) Cardiovascular system: vasodilation, hypotension, positive chronotropic and inotropic effects [1434].
2) Respiratory system: bronchodilation, augmented ventilation, pulmonary vasodilation, stimulation of bronchial secretion (VIP and asthma [1435]).
3) Gastrointestinal tract: relaxation of lower esophageal sphincter; relaxation of smooth muscle in the stomach and suppression of acid secretion; stimulation of pancreatic water and HCO_3 secretion; increased bile flow; inhibition of intestinal absorption; stimulation of intestinal water and chloride secretion; relaxation of circular muscles and contraction of longitudinal muscles in the colon [1436], [1437].
4) Urogenital tract: increase of blood circulation in the vagina and erection of the penis.
5) Metabolic effects: stimulation of glycogenolysis and lipolysis, bone resorption, hair growth [1438]; regulation of mitosis, differentiation and survival of cultured sympathetic neuroblasts [1439]; stimulation of in vitro meiosis in follicle-enclosed rat oocytes [1440]; and regulation of neuronal survival.
6) Endocrine functions: increased pituitary release of ACTH, prolactin [1441], growth hormone, and LH; suppression of somatostatin release; an increased release of gonadoliberin in the hypothalamus and of iodine-containing hormones in the thyroid; ACTH-like action in the adrenals (stimulation of aldosterone and corticosterone synthesis [1442]); increase of serum testos-

terone and dihydrotestosterone in women [1443]; increased aromatase activity in the neonatal rat ovary [1444]; increase of serum estradiol in women [1443]; stimulation of estradiol and progesterone release from rat ovaries [1445]; and stimulation of testosterone, progesterone, and pregnenolone release in cultured neonatal testicular cells [1446].

Structure – Activity Relationships. The C-terminal amide is not required for the biological activity of VIP; deamido^{28}-VIP, VIP-Gly, and [Leu^{17}]VIP-Gly-Lys have similar activities [1447]. Shortening the molecule at either the C- and N-terminus decreases biological activity. VIP-(10 – 28) exerts an antagonistic effect on the VIP-stimulated synthesis of cAMP and secretion of pepsinogen [1448]. Met^{17} can be replaced by norleucine without loss of activity.

The hydrophobic amino acids of the helical domain (6 – 28) are important for receptor binding, the hydrophilic amino acids in this region appear to be less important. Substitutions of the amino acids in positions 6, 10, 12, 17, 19, 22, 23, and 27 produce less active derivatives [1449]. Iodination leads to at least two VIP derivatives with full biological activity [1450].

Displacement of [^{125}I]VIP bound to receptors on rat liver membranes by various analogues occurs in the following order: VIP > [D-Ala^4]VIP > [D-Asp^3]VIP > [D-Ser^2]VIP > [D-His^1]VIP > [D-Phe^2]VIP > [D-Arg^2]VIP. [D-Phe^2]VIP is a competitive VIP antagonist, the other analogues have agonistic activity [1451]. Still better VIP antagonists are [D-4-ClPhe^6,Leu^{17}]VIP [1452] and Ac-[Tyr^1,D-Phe^2]GHRH-(1 – 29)amide [1453]. [D-Phe^4]PHI-27 is a highly selective VIP agonist [1454].

7.3. Pituitary Adenylate Cyclase Activating Polypeptide (PACAP)

Occurrence. There is considerable homology between VIP and o-PACAP-38 [1455] and o-PACAP-27 [1456], two peptide amides from the sheep hypothalamus. The prepropeptide of h-, o- [1457], and r-PACAP [1458] has been characterized via the cDNA. Highly specific receptors have been found primarily in the hypothalamus, brain stem, cerebellum, and lung. PACAP-27 binds more tightly than PACAP-38.

In the rat hypophysis, o-PACAP-38 and o-PACAP-27 stimulate adenylate cyclase 1000 times more effectively than VIP [1455], [1456]. Like VIP, o-PACAP-27 exhibits vasodepressor activity [1456]. Concentrations of 10^{-10} mol/L release growth hormone, prolactin, and ACTH from rat hypophyseal cells, 10^{-9} mol/L releases LH as well [1459].

7.4. Glucagon and Related Peptides

Glucagon (GG) is formed together with the two glucagon-like peptides, GLP-1 and GLP-2, as prepro-GG (r- [1460], h- [1461], b- [1462], p- [1463]). Glucagon is prepro-GG-(33 – 61), GLP-1 is prepro-GG-(72 – 108), and GLP-2 is prepro-GG-(126 – 159). In the pancreatic A-cells, prepro-GG is cleaved to GG and longer C-terminal peptides that contain GLP-1 and GLP-2. In the small intestine, however, prepro-GG is cleaved to form glicentin [prepro-GG-(1 – 69)], enteroglucagon [prepro-GG-(33 – 69)], GLP-1, and GLP-2 [1464]. In the small intestine the six N-terminal amino acids of GLP-1 are removed to give the C-terminal amide GLP-1-(7 –36)amide [prepro-GG-(78 – 107)amide] [1465].

The sequences of h-prepro-GG [1461] and its cleavage products are shown in Figure 5.

7.4.1. Glucagon

Glucagon (GG) [*642-83-1*], M_r 3483 (h-GG), is formed in the endocrine A- cells of the pancreas. It is, however, also found in the rat pituitary.

Release. Pulsatile GG release is observed in humans at 13 – 20 min intervals [1466]. The Ca^+-dependent secretion of GG is stimulated by amino acids, stress [1467], β-endorphin [1468], morphine [1469], dopamine, carbachol, cholecystokinin [1470], bombesin, xenopsin, substance P, and high doses of oxytocin and vasopressin. Parathyroid hormone potentiates the arginine-stimulated release of GG.

GG secretion is inhibited by glucose [1471], Mg^{2+}, thyroliberin, calcitonin, SRIH, glicentin-(1 – 16), glicentin-(62 – 69) [1472], and sulfonyl

Figure 5. Amino acid sequences of h-prepro-GG and its cleavage products

urea derivatives, e.g., glibenclamide [1473]. The plasma level of GG is elevated in overweight persons [1474] and is reduced in type I diabetics [1475].

Biological Effects [1476]. Glucagon plays a role in carbohydrate, fat and protein metabolism. In the liver, its most important target organ, GG stimulates the formation of glucose from glycogen (glycogenolysis) and of ketone bodies from amino acids. Glycogen synthesis is simultaneously inactivated via a phosphorylation reaction [1477] and the binding of insulin in the liver is reduced [1478]. Intracerebroventricular administration of GG increases blood glucose levels via cholinergic and α-adrenergic mechanisms much more than intravenous administration [1479].

In hepatocytes, GG inhibits fatty acid synthesis via activation of a cAMP-dependent protein kinase and subsequent phosphorylation of an acetyl coenzyme A (CoA) carboxylase [1480]. It stimulates lipolysis in brown adipose tissue [1481]. It reduces the activity of β-hydroxy-β-methylglutaryl CoA reductase [1482] and lowers the plasma level of apolipoprotein E, cholesterol, triacyclglycerol, and phospholipids [1483].

Other effects of GG include stimulation of the plasma level of cAMP, reduction of the blood levels of Ca^{2+} and PO_4^{3-}, spasmolytic activity in high doses, relaxation of the esophagus, contraction of the pyloric sphincter [1484], relaxation of the Oddi sphincter [1485], stimulation of bile flow [1486], bronchodilatory effect in asthmatic patients [1487], and inhibition of anaphylactic histamine release.

Structure – Activity Relationships. The shortening of GG and the replacement of its N-terminal histidine reduces glycogenolytic activity [1488]. GG-(1 – 21) is fully active as regards spasmolytic activity but only about 0.1 % as active as regards cAMP-releasing activity. Thus, GG-(1 – 21) exerts a relaxing effect on the Oddi sphincter [1489] and an analgesic effect in biliary colic [1490]. Further shortening of the compound, e.g., GG-(1 – 20) and GG-(2 – 21), reduces the spasmolytic activity to $\leq 2\,\%$ of the GG activity. GG-(19 – 29) does not activate adenylate cyclase, but is 1000 times more active than GG in inhibiting the Ca^{2+}-activated and Mg^{2+}-dependent ATPase [1491] and the liver plasma membrane calcium pump [1492].

Substitutions in the N-terminal region of GG usually lower biological activity. However, [D-Ser^2]GG [1493] and [D-Phe^4]GG had twice and six times the glycogenolytic activity in the rat, respectively [1494].

The amino acid region 10 – 13 is not essential for biological activity, but is important for receptor binding [1495].

S-Methylation of Met^{27} reduces glucagon activity to 1 %; [*S*-carboxymethyl-Met^{27}]GG [1496], [2-thiol-Trp^{25}]GG, [oxindolyl-Ala^{25}] GG, [$Met(O_2)^{27}$]GG, monoiodo-GG and [*N*-ε-alkylamidino-Lys^{12}]GG are fully active.

N-α-Trinitrophenyl-GG and *N*-α-trinitrophenyl-[12-homoarginine]GG are weak antagonists that exert a partially agonistic effect. Antagonists include de-His^1-[Glu^9]GG-amide [1497], de-His^1-[Glu^9,Orn^{12}]GGamide, de-His^1-[Glu^9,Glu^{16},Lys^{29}]GG-amide, de-His^1-[Glu^9,Lys^{29}]GG-amide [1498], [Asp^3,D-Phe^4, Ser^5, $Lys^{17,18}$,Glu^{21}]GG, and [D-Phe^4,Tyr^5,I_2-Tyr^{10},Arg^{12}, $Lys^{17,18}$,Glu^{21}]GG [1499].

Uses. Glucagon (Glucagon Novo, Novo Ind.; Glukagon Lilly, Eli Lilly) is used to treat hypoglycemia. In McArdle's disease, subcutaneous injection of glucagon increases the blood sugar level and thus improves muscle function.

The spasmolytic activity of GG facilitates endoscopic and radiological investigations of the gastrointestinal tract and computer tomography of the liver, pancreas, and kidney. GG can also bring relief to persons suffering from esophageal cramps [1500] and hiccups [1501]. Its spasmolytic activity in combination with the enhanced flow of bile has been useful in the treatment of biliary colic.

As a result of its effect on the plasma Ca^{2+} level, glucagon has been used in combination with calcitonin and mithramycin in the treatment of Paget's disease.

GG can be applied parenterally (also with a portable pump [1502] or as a depot preparation [1503]), nasally [1504], or as eye drops [1505].

7.4.2. Glicentin and Enteroglucagon

Glicentin [*71567-776*], M_r 8101, [h-prepro-GG-(1 – 69)] and enteroglucagon [*62340-29-8*], M_r 4450, also called oxyntomodulin [h-prepro-GG-(33 – 69)], are synthesized in the small intestine from prepro-GG [1464]. The plasma level of glicentin rises during hypoglycemia [1506] and physiological doses of both peptides decrease the secretion of gastric acid [1507]. Glicentin has only 10 % of the cAMP-stimulating activity of GG. Thus, glicentin and enteroglucagon assume the function of a hypothetical enterogastrone in the intestine (an enterogastrone is a substance formed in the intestine which decreases gastric acid release). The common C-terminal octapeptide appears to be especially important for activity and can inhibit the pentagastrin-stimulated secretion of gastric acid (although 100 times weaker) [1508].

Enteroglucagon is also 10 times more active than GG in inhibiting cerulein-stimulated exocrine pancreatic secretion in rats [1509].

7.4.3. Glucagon-Like Peptide-1-(7 – 36)amide

The peptide GLP-1 is processed primarily in the small intestine to give the C-terminal amide GLP-1-(7 – 36)amide, M_r 3298 (h-GLP-1-(7 – 36)-amide) [1465].

Release. Intestinal release of GLP-1-(7 – 36)amide is stimulated by orally applied glucose, D-galactose, D-glucuronic acid, 3-*O*-methyl-D-glucose, maltose, sucrose, or maltitol [1510]. Fructose, D-fucose, D-mannose, D-xylose, and lactose have no effect [1510]. The postprandial increase in the plasma level of GLP-1-(7 – 36)amide is enhanced in the post-gastrectomy dumping syndrome [1511].

Receptors. GLP-1-(7 – 36)amide binds specifically to a cloned, insulin-producing cell line from the rat. Even micromolar concentrations of GLP-1-(1 – 36)amide or GIP do not displace GLP-1-(7 – 36)amide from the receptor [1512]. Dexamethasone reduces the number of GLP-1-(7 –36)amide receptors on the B-cells [1513].

Biological Effects. GLP-1-(7 – 36)amide is more effective in stimulating cAMP synthesis in rat preparations than GLP-1 or glucagon [1514], [1515]. GLP-1-(7 – 36)amide is more active than GLP-1 in stimulating the glucose-dependent release of insulin from pancreatic islet cells of the rat [1515]. Tests on humans have shown that GLP-1-(7 – 36)amide has the properties of inkretin (a hypothetical substance that stimulates the glucose-dependent endocrine secretion from the pancreas): its formation in the gastrointestinal tract is enhanced after an oral glucose meal, it releases insulin in a glucose-dependent process, and lowers the plasma levels of glucose

and glucagon [1511]. GLP-1-(7 – 36)amide and GIP have a synergistic effect on the release of insulin [1516] but not in the stomach. In the pancreas GLP-1-(7 – 36)amide inhibits the secretion of glucagon by post-transcriptional mechanisms and decreases the secretion of somatostatin [1517], [1518].

Structure – Activity Relationships. The amide structure of GLP-1-(7 – 36)amide is apparently not essential for its insulin-releasing activity. GLP-1-(7 – 37) is as active as GLP-1-(7 – 36)amide [1519].

Uses. In type II diabetes (non-insulin-dependent), GLP-1-(7 – 36)amide stimulates the release of insulin and inhibits the secretion of glucagon and somatostatin. Both in type I (insulin-dependent) and type II diabetes, the isoglycemic-meal- related insulin requirement is lowered by GLP-1-(7 – 36)amide [1520].

7.5. Gastrin Inhibiting Peptide

Occurrence. The gastrin inhibiting peptide (GIP) [*59392-49-3*] also known as the glucose-dependent insulinotropic peptide, M_r 4984, contains 42 amino acids and is found in the duodenum, jejunum, and together with glucagon in the A-cells of the pancreas.

Release. GIP is secreted in the duodenum and jejunum in response to a diet rich in fat and carbohydrate. The pancreatic enzymes are also involved in stimulating this release [1521]. During physical exercise, the secretion of GIP in response to orally administered glucose is greatly reduced [1522]. The effect of GIP is enhanced by bombesin or low doses of motilin. High doses of motilin, somatostatin, and dexamethasone inhibit the release of GIP [1523].

The raised level of GIP in insulin-dependent (type I) diabetes can be lowered with insulin [1524]. This is, however, not the case with non-insulin-dependent diabetes mellitus [1525]. The postprandial plasma level of GIP is low in obese, non-insulin-dependent diabetics [1526].

Biological Effects. GIP inhibits the gastrin-stimulated secretion of gastric acid, as well as the secretion of pepsin, and motor activity in the stomach. It stimulates the intestinal secretion and increases the glucose-dependent release of insulin, glucagon, pancreatic peptide, and somatostatin in the pancreas. cAMP is activated in this process. The GIP-mediated release of insulin is dependent on phospholipase A_2 [1527] and is linked to a cholinergic mechanism [1528].

In adipocytes, GIP increases the receptor affinity for insulin [1529] and potentiates the inhibitory effect of insulin on hepatic glycogenolysis [1530].

The physiological importance of GIP is probably based on its insulinotropic activity rather than on the reduction of the gastric acid concentration. Like GLP-1-(7 – 36)amide, GIP is an important candidate for the role of the postulated inkretin.

Structure – Activity Relationships. Shortening the molecule at the N-terminus by only two amino acids reduces the insulin-releasing effect to about 2 %. Endo-29a-Gln-GIP-(1 – 38) and b-GIP-(1 – 39) [1531] still possess full insulinotropic activity. GIP-(1 – 28) and GIP-(3 – 24) do not release insulin [1532].

7.6. Growth Hormone Releasing Hormone and the Growth Hormone Cascade

The growth hormone cascade is shown in Figure 6. The growth hormone releasing hormone or somatoliberin (GHRH or SRH) and galanine (GAL) stimulate the release of the growth hormone (also known as somatotropin, STH) from the pituitary which, in turn, releases the somatomedins (SMs). Somatostatin (SRIH), which inhibits the release of GHRH and GH, is of great importance in the regulation of growth hormone. GAL inhibits the release of SRIH, which promotes the release of GHRH and GH. GHRH and GH stimulate the synthesis of SRIH and thus permit a negative feedback. A synthetic hexapeptide (SK&F 110 679) also releases GH from the pituitary, independently of GHRH receptors.

Figure 6. The growth hormone cascade
GAL = galanine; GH = growth hormone (somatotropin); GHRH = growth hormone relesing hormone (somatoliberin); IGF-I = insulin-like growth factor I; SRIH = somatotropin release inhibiting hormone (somatotropin)

There is a high degree of structural similarity between GH and placental lactogen, somatolactin, prolactin, proliferin, and prolactin-related or -like proteins. The insulin-like growth factors, IGF-I (somatomedin C) and IGF-II, as well as somatomedin B belong to the somatomedins. Insulin and relaxin are structurally related to IGF-I and IGF-II.

7.6.1. Galanine [1533]

Occurrence. Galanine (GAL) [*119418-04-1*], M_r 3211 (p-GAL), was first isolated from the pig intestine [1534]. Its name is derived from its N- and C-terminal amino acids (glycine and alanine). It is a 29 amino acid peptide amide with a C-terminal that is similar to the neurokinins, e.g., neurokinin A or substance P. Both p- and b-GAL are processed in the form of a prepropeptide containing 123 amino acids [1535].

In humans, GAL is not only found in the nerve cells of the small intestine, but also in the brain, spinal cord, pancreas, bladder, pituitary [1536], adrenal gland [1537], and the genital tract [1538]. In the central nervous system, the highest concentrations are found in the hypothalamus [1539] and the median eminence. Unusually high concentrations of GAL are found in pheochromocytomas [1540].

GAL is localized with gonadoliberin in neurons of the hypothalamus [1541].

Release. The release of GAL in the adenohypophysis and hypothalamus is stimulated by estrogen [1536] and the thyroid hormones, e.g., T_4 [1542]. The formation of GAL decreases after the withdrawal of food [1543] and treatment with capsaicin.

Biological Effects. GAL contracts preparations from the rat fundus, ileum, colon, bladder [1534], and jejunum [1544]. It potentiates the contraction of the rat vas deferens that is induced by electrical stimulation or noradrenaline [1545]. GAL inhibits, however, contraction induced by electrical stimulation in the guinea pig colon. It also inhibits the motility of the small intestine in the rabbit. GAL inhibits the release of acetylcholine and substance P from motor nerves [1545] and transmission at the cholinergic nicotinic synapses in the myenteric plexus [1546].

In humans, GAL inhibits gastrointestinal motiliy, delays gastric emptying, and increases the mouth to cecum transit time. It also suppresses the postprandial increase in glucose, PYY, insulin, neurotensin, enteroglucagon, glucagon, pancreatic peptide (PP), and somatostatin (SRIH) levels [1547]. GAL directly inhibits the exocytosis of insulin [1548]. Glucagon is stimulated in vitro. In mice, GAL inhibits the basal and stimulated insulin level, increases the plasma glucagon level temporarily and causes hyperglycemia [1549]. In the perfused porcine pancreas, however, GAL increases the release of insulin and inhibits the secretion of SRIH [1550].

GAL inhibits the release of gastrin and SRIH [1551] and the pentagastrin-stimulated secretion of gastric acid from the rat stomach [1552].

The intracerebroventricular application of GAL to rats or the intravenous infusion in humans increases the plasma levels of growth hormone and prolactin [1539] via the release of adrenaline [1553] and GHRH [1554], or via the inhibition of SRIH. It acts synergistically with GHRH [1555].

In rats, injections of GAL into the paraventricular nucleus cause an increase in the food

uptake. It protects hippocampal neurons from the functional effects of anoxia [1556].

Structure – Activity Relationships. The molecule can be shortened at the C-terminus without loss of activity; in contrast, deletions at the N-terminus result in complete loss of activity.

GAL-(1 – 10) strongly contracts the rat jejunum, but it does not inhibit the electrically stimulated contraction of strips of guinea pig colon [1544]. The action of GAL-(1 –20) is species and muscle dependent, and is similar to or weaker than that of GAL [1557]. While GAL-(1 – 16) has an agonistic effect on the rat hippocampal GAL receptor, GAL-(3 – 29) [1558] and GAL-(17 – 29) [1559] are inactive. The effect on the guinea pig ileum is as follows: GAL > GAL-(2 – 9) > GAL-(1 – 15) [1560]. In rats, the pentagastrin-stimulated secretion of gastric acid is inhibited by GAL-(9 – 29) with 5 % of the GAL activity, while GAL-(15 – 29) is devoid of activity [1552].

7.6.2. Growth Hormone Releasing Hormone [1561]

Occurrence. In humans, growth hormone releasing hormone (GHRH) [*9034-39-3*], also called somatotropin releasing hormone (SRH) or somatoliberin, M_r 5040 (h-GHRH), is a peptide amide containing 44 amino acids. Although GHRH is mainly synthesized in the hypothalamus, immunoreactive GHRH has also been found in the gastrointestinal tract, placenta, human and rat milk, and spinal fluid [1562].

In the neurons of the arcuate nucleus, GHRH is associated with NPY [1563], dopamine [1564], and tyrosine hydroxylase [1565].

During the processing of prepro-h-GHRH, prepro-h-GHRH-(78 – 107)amide with a pyroglutamyl residue at the N-terminus (CTPG or anorectin) is formed. This peptide reduces the intake of food when injected into the third ventricle [1566].

Release. The release of GHRH is stimulated by central α_2-adrenergic stimuli, high potassium concentrations, GABA, opioids, galanine [1567], dopa [1568], thyroid hormones, and by a glucose meal [1569]. More GHRH is found in the hypothalamus of male rats than in female rats [1570]. The plasma level of immunoreactive GHRH increases greatly during puberty (more so in girls than in boys) [1571].

Somatostatin (SRIH) and pentobarbital anesthesia inhibit the secretion of GHRH. Growth hormone [1572], insulin-like growth factors IGF-I and IGF-II [1573], GHRH itself [1574], and dopamine also inhibit the release of GHRH by increasing SRIH release. The GHRH-stimulated secretion of SRIH is presumed to be regulated by β-endorphin-containing neurons [1575].

The plasma level of GHRH is lower in children suffering from dwarfism and in acromegaly [1576]. Less GHRH is found in the hypothalamus of old rats than in young rats [1577].

Receptors. Chronic infusion (in vivo) of GHRH [1578] and adrenalectomy [1579] lead to the down regulation of GHRH receptors in the rat.

Biological Effects. GHRH stimulates transcription of the GH gene and the release of GH [1580] in the pituitary via an increase in cAMP, arachidonic acid, and PGE_2. Chronic administration does not totally inhibit the release of GH [1581]. It is assumed that melatonin [1582], cholinergic agonists [1583], β_1-adrenergic receptor blockers [1584], and hypoglycemia [1561] increase the GHRH-stimulated GH level via the inhibition of SRIH release. The GHRH-stimulated release of GH is inhibited by SRIH, cholinergic antagonists [1583], α-receptor blockers [1585], dopamine [1586], hyperglycemia [1587], and by IGF-I and II [1573]. The GHRH-induced release of GH is reduced in children with thalassemia major [1588], in patients suffering from non-insulin-dependent (type II) diabetes [1589], hypothyroidism [1590], Cushing's syndrome [1591], depression [1592], and obesity [1561]. The GHRH-stimulated secretion of GH is raised in diabetics with retinopathy [1561], in acromegaly, and in young Alzheimer patients [1593]. In patients with hypothyroidism, T_4 potentiates the GHRH-induced release of GH [1590].

Glucocorticoids exert a biphasic effect on the release of GH. They potentiate GHRH activity

by stabilizing the GHRH receptors and enhancing the transcription rate of the GH gene. In cases of chronic misuse of glucocorticoids, however, an inhibition of the release of GH is observed in humans and experimental animals [1594].

Other effects of GHRH include release of calcitonin and neurotensin from rat C-cells [1595], proliferation of endothelial cells in the mucosa of the fundus and antrum [1596], increase in the production of milk in cows and sheep, and increase in REM sleep [1597].

Structure – Activity Relationships. GHRH can be shortened at the C-terminus without loss of activity. In rats, h-GHRH-(1 – 29)amide has 50 % of the activity of h-GHRH-(1 – 44)amide. However, h-GHRH-(1 – 29)amide has the same activity as h-GHRH-(1 – 44)amide in children [1598]. Further shortening at the C-terminus significantly reduces activity [1599]. The N-terminal amino group is of no importance for biological activity because its acetylation gives more potent compounds.

Position 1 should be occupied by an aromatic amino acid [1600]. Nle^{27} and D-Ala^2 increase activity. Although [D-Ala^2]GHRH-(1 – 29)amide had 50 times the activity in some tests and Ac-[D-Tyr^1,D-Ala^2]-GHRH-(1 – 29)amide had 38 times the GHRH-(1 – 29)amide activity in the rat, these compounds do not exhibit a higher activity in humans [1601]. The replacement of Arg^{29} by agmatin (Agm) increases activity. Potent long-acting analogues are [D-Ala^2,Nle^{27}]h-GHRH-(1 – 28)Agm [1602] and [deamino-Tyr^1,Ala^{15},Nle^{27}]GHRH-(1 – 28)Agm [1603].

[D-Arg^2]h-GHRH-(1 – 29)amide exhibits GHRH antagonistic activity in concentrations of 10^{-7} mol/L [1604]. More potent antagonists are [D-$Arg^{2,29}$,Arg^{30}]h-GHRH-(1 – 30)amide and Ac-[His^1,D-Arg^2,Ala^{15}]r-GHRH-(1 – 29)amide [1605].

An antagonist that acts in the 10 µmol/L range is [Ser^9-ψ-CH_2NH-Tyr^{10}]GHRH-(1 – 29)amide [1606].

The activity of h-GHRH-(1 – 27)amide can also be increased: [D-Asp^3,D-Asn^8,Leu^{27}]h-GHRH-(1 – 27)amide has twice the activity of h-GHRH-(1 – 29)amide [1607].

Uses. GHRH can be used as a diagnostic aid to differentiate between hypothalamic- and hypophyseal-dependent growth hormone deficiency diseases. Only patients with a defective hypothalamus usually react to GHRH by producing GH. The older the patient (i.e., the longer the endogenous GHRH deficiency disease exists) the poorer the reaction of the hypophysis.

GHRH is used in the treatment of children with GH deficiency. The linear growth of children was improved by subcutaneous administration of 250 µg of GHRH-(1 – 29)amide twice a day [1608] or after pulsatile treatment (subcutaneous application of 1 – 3 µg/kg every 3 h) [1609]. Children suffering from dwarfism responded better to h-GH than to h-GHRH-(1 – 29)amide [1610]. In postmenopausal women GHRH increases bone formation and plasma osteocalcin [1611].

Of the large number of smaller synthetic peptides [1612], one of the most active is the hexapeptide amide SK&F 110 679 (sequence: H w A W f Ka), which has about 10 % of the GHRH activity [1613]. There is no structural similarity between this peptide and GHRH. It releases GH from hypophyseal cell cultures in vitro and acts synergistically with GHRH. Thus, it evidently does not bind to the same receptor as GHRH [1614]. In humans, doses as low as 0.25 – 1 µg kg^{-1} 30 min^{-1} stimulate the release of GH. The compound appears to be more effective in this experiment than GHRH [1615].

7.6.3. Growth Hormone, Placental Lactogen, and Prolactin

The pituitary hormones prolactin (PRL) and growth hormone (GH) are structurally related to placental lactogen (PL) and two GH variants (GH-V and GH-V2) from the placenta. PL has lactogenic properties and some somatotropic activity (tibia test). PRL has no somatotropic activity, but GH has weak PRL activity.

Other substances related to PRL are somatolactin (pl-SL) [1616], proliferin (m-PLF), prolactin related cDNA (b-PRC I, II, and III), proliferin related protein (m-PRP), and prolactin-like proteins (r-PLP A and B, b-PLP I, II, and III) [1617].

There is great similarity in the structures of secretin-(5 – 20), h-GH-(1 – 16), and h-PL-(1 – 16). There is also amino acid homology

between h-GH-(30 – 38), gastrin, and the C-terminus of the B-chain of insulin.

7.6.3.1. Growth Hormone

Occurrence. Growth hormone (GH) [*9002-72-6*], also known as somatotropin (STH), M_r 22 125 (h-STH), has 191 amino acids and is formed in the pituitary as pro-GH. Circulating GH occurs in several forms: monomeric (little GH), dimeric (big GH) and oligomeric (big-big GH, $M_r > 60\,000$) [1618]. In addition, 20Kh-GH, a de-(32 – 46)GH, and the two GH variants from the placenta, GH-V and GH-V2 [1619] have also been found. The amino acid sequences of GH in various species are described in [1620], [1621].

Release [1622]. GH is regulated primarily by the hypothalamic hormones galanine (GAL, see Section 7.6.1), growth hormone releasing hormone (GHRH, see Section 7.6.2), and somatostatin (SRIH, see Section 7.6.5). GAL and GHRH stimulate and SRIH inhibits the pituitary release of GH. Treatment with SRIH enhances the GHRH-stimulated release of GH [1623]. GH is also released in response to stimulation of α_1-adrenergic receptors [1624] and cholinergic muscarinic receptors [1625], inhibition of α_2-adrenergic receptors [1626], SKF-110 679, insulin, hypoglycemia, glucagon, arginine, physical stress [1627], α-melanotropin, opioids [1628], angiotensin II [1629], pentagastrin [1630], GIP, neurotensin, combined application of thyroliberin with ACTH [1631], slow wave sleep [1632], intracerebroventricular application of delta-sleep-inducing peptide, interleukin-1β [1633], serotonin [1634], dopamine and dopamine agonists [1635], and indomethacin [1636].

In women, the release of GH is dependent on estrogen. Thus, the plasma level of GH falls during menopause [1637] and in suppression therapy with high doses of GnRH agonists [1638]. In young hypogonadal males, testosterone stimulates the GH formation and growth [1639]. Glucocorticoids also regulate the synthesis of GH. Hypoadrenalism [1640] and high doses of glucocorticoids [1641] lower the release of GH. However, glucocorticoids and triiodothyronine (T_3) enhance the release of GH in vitro through GHRH.

GH release is inhibited by recombinant Met-GH [1642], centrally applied gastrin releasing peptide [1643], corticoliberin [1644], calcitonin [1645], calcitonin gene related peptide [1646], and by TRH [1647], mainly via the secretion of SRIH.

Plasma GH levels in persons with acromegaly and type I diabetes [1648] are higher than in healthy persons, but are reduced in depressive patients with an increased level of somatomedin C [1649]. TRH has no influence on the release of GH in normal subjects, but it causes a paradoxical increase in the plasma level of GH in patients suffering from acromegaly [1650], depression [1651], or metastatic testicular cancer [1652]. GnRH also raises the plasma GH level in type I and type II diabetics [1653].

Receptors. The amino acid sequences of the GH receptors from humans, rabbits [1654], and rats [1655] have been elucidated via their cDNA.

GH binding proteins are mainly the extracellular fragments of GH receptor [1656]. In patients with Laron-type dwarfism (high plasma GH level and low IGF-I level), the GH receptor is defective [1657] and the high-affinity GH binding protein is missing [1658]. African pygmies have a low plasma level of GH-binding protein [1659].

Biological Effects. GHRH is species specific and promotes the longitudinal growth and regeneration of bone. It has a strong mitogenic effect on osteoblasts [1660] and pancreatic β-cells [1661], increases the osteocalcin level [1662], and enhances DNA, RNA, and protein synthesis. It possesses lipolytic, diabetogenic, and insulinotropic properties; it also has an antidiuretic and antinatriuretic effect because it activates renin and increases the plasma level of aldosterone [1663].

In a negative feedback mechanism, GH inhibits the release of GHRH in the hypothalamus [1664] via the release of SRIH [1665].

Pulsatile intravenous GH stimulates the formation of somatomedin C [1666] in the liver and skeletal tissue. This substance is identical to the insulin-like growth factor I (IGF-I) and is largely responsible for the growth effect of GH [1667].

In vitro, GH stimulates the release of insulin from pancreatic islet cells [1668] and the insulin-dependent uptake and oxidation of glucose in adipose and muscle tissues [1669]. The insulin-like effect of GH is only found in vivo in GH deficiency models or children suffering from GH deficiency. Chronic therapy with GH or very high doses of GH have a diabetogenic effect in hypophysectomized animals. After prolonged GH treatment the fasting plasma glucose level in humans is raised [1670] and in patients with acromegaly, glucose metabolism is reduced in spite of the increased release of insulin [1671].

Physiological doses of GH also stimulate the production of peroxide anions in macrophages. It increases the activity of cytolytic T-cells and of natural killer cells, stimulates the formation of antibodies and thymulin synthesis [1672], and regenerates the thymus in dogs [1673].

Structure – Activity Relationships. Similar to h-GH, recombinant Met-h-GH, which acts like natural h-GH in children with GH deficiency [1674], has diabetogenic and insulin-like activity [1675]. Met-h-GH has a somewhat higher tendency to initiate antibody formation [1676]. Other acidic GH derivatives (deamidated h-GH) are as active as h-GH [1620].

The epiphyseal plate of the long bones of the rat declines following hypophysectomy and increases after treatment with GH. This increase in the width of the plate of the proximal end of the tibia has been used for the quantitative measurement of GH. Various GH fragments exhibit biological activity in the tibia test in hypophysectomized animals, e.g., GH-(88 – 124), GH-(125 – 156), b-GH-(96 – 133), and GH-(151 – 191). h-GH, but not 20K-h-GH, reduces the concentration of free fatty acids in children deficient in GH [1677]. The binding of 20K-h-GH to lactogenic receptors is about 500 times less than that of GH [1678]. The lactogenic activity of h-GH and o-PRL is competitively inhibited by [Met^{14}]h-GH-(14 – 191) [1621].

h-GH-(4 – 15) and h-GH-(6 – 13) stimulate glucose oxidation, glucose uptake in adipose tissue, and the synthesis of glycogen [1679]. The minimal GH sequence with this insulin-potentiating effect is h-GH-(8 – 13). An artifact, the aspartoylimide variant of these peptides, appears to be responsible for this effect [1680]. Other insulinotropic GH fragments are h-GH-(31 – 44), h-GH-(32 – 38) [1681], and h-GH-(32 – 46) [1682]. Both h-GH-(177 – 191) and h-GH-(178 – 191) have diabetogenic activity.

Uses. Met-h-GH and h-GH are produced by genetic engineering and are now used instead of natural h-GH in the therapy of hypophyseal dwarfism. Trade names include Genotropin (Pfrimmer Kabi), Grorm, Saizen (Serono), Humatrop (Lilly), and Norditropin (Nordisk).

h-GH has also been used to activate growth in persons with Turner's syndrome where growth is reduced in spite of normal GH formation [1683]. h-GH also finds application for the healing of wounds [1684] and for increasing the mass [1685] and density of bones [1686]. In older patients with low plasma GH levels, GH increases bone density, lean body mass, and skin thickness, and reduces the amount of adipose tissue [1687].

7.6.3.2. Prolactin

Occurrence. Prolactin (PRL) [*9002-62-4*], M_r 22 806 (h-PRL, protein part), has 198 amino acids and is formed in the pituitary where it is glycosylated at Asn^{31} [1688] or dimerized via disulfide bridges [1688]. Other sites of synthesis are the placenta, myometrium, ovaries [1689], and hypothalamus. The sequences of PRL from various species are listed in [1690].

Release [1691]. The pulsatile secretion of PRL from the pituitary is regulated by hypothalamic factors. It is stimulated by TRH and VIP and inhibited by dopamine. The C-terminal glycopeptide of vasopressin-neurophysin, which contains 39 amino acids, is a specific PRL-releasing factor [1692]. PRL is also released in response to K^+ [1693], hypocalcemia [1694], calcitriol [1695], cholecystokinin, insulin, arginine [1696], epidermal growth factor [1697], the sucking stimulus through endogenous opioids [1698] and VIP [1699], stress and physical exercise [1700] through serotoninrgic mechanisms [1701], β-endorphin [1702], AT II [1703], gonadoliberin [1704] through the formation of AT II [1705], neurotensin [1706], and to glutamate [1707]. It is also released by the stimulation of α_1-adrenergic receptors [1708] or histamine H_1-receptors [1709].

Dopamine from the hypothalamus and pituitary [1710] which is released by PRL is probably one of the most important inhibitors of PRL release.

The secretion of PRL is also inhibited by ascorbic acid [1711], δ opiates [1712], hypercalcemia [1713], the prolactin inhibiting factor (PIF), PRL itself [1714], stimulation of α_2-adrenergic [1708], GABA-A- [1715], or histamine H_2-receptors [1709], chronic nicotine intake [1716], somatostatin and its analogues [1717], calcitonin [1718], IL-1 [1719], T_3 [1720], melatonin [1721], glucocorticoids [1722], vasopressin (presumably via a dopaminergic pathway [1723]), and central neurotensin. A competitive antagonist of PRL is a recombinant h-GH, which lacks the 13 amino acids at the N-terminus [1724].

The steroid sex hormones modulate the release of PRL. Estrogen potentiates the secretion of PRL in experimental animals [1725], but can also potentiate the dopamine-stimulated inhibition of PRL release in humans. 17-β-estradiol potentiates the somatostatin-stimulated inhibition of PRL in pituitary cells [1726]. Testosterone appears to inhibit the secretion of PRL because the TRH-stimulated release of PRL is greatly enhanced in delayed puberty (males) [1727].

A period of breast feeding is followed by a reduced PRL level for at least 12 – 13 years [1728], which could be related to the low risk of breast cancer after pregnancies. Women who are not lactating have a pronounced PRL deficiency [1729]. In humans, the PRL response to TRH falls with age [1730]. Patients with chronic kidney damage and rats with experimentally induced kidney damage develop hyperprolactinemia. The plasma level of PRL is raised in spontaneously hypertensive rats and in patients with hypertension.

Receptors. Receptors for PRL are widely distributed: in the mammary gland, liver, kidneys, brain, prostate, testes, ovaries, and lymphocytes [1731]. The receptors have a similar structure to that of the GH receptors [1732], [1733].

In the rat, the number of PRL receptors in the mammary gland increases on the day of estrus. Together with estradiol, LH stimulates the formation of PRL receptors [1734]. The number of testicular PRL receptors in the golden hamster is increased by PRL, FSH, and LH; ovariectomy and hypophysectomy reduce the synthesis of PRL receptors [1735].

PRL is displaced from the receptors on lymphocytes by cyclosporin [1731].

Biological Effects. In female mammals, PRL increases the production of milk and initiates maternal behavior. The PRL-stimulated biosynthesis of casein and lipid is reduced by inhibitors of phospholipase A_2 [1736].

PRL stimulates the synthesis of dopamine and increases the density of dopamine receptors [1737]. Thus, the dopamine level in the central nervous system and the dopaminergic inhibition of aldosterone are increased in patients suffering from hyperprolactinism [1738].

Similar to placental lactogen, PRL also has luteotropic properties and stimulates the synthesis of progesterone [1739], but inhibits the formation of estradiol and testosterone [1739]. In men with chronically elevated PRL levels, the plasma level of testosterone is low and the excretion of LH in the urine is reduced [1740]. In women, hyperprolactinemia leads to irregular menstruation or even amenorrhea [1741].

PRL increases the blood pressure of experimental animals which is dependent on the adrenal glands and presumably occurs via the potentiation of noradrenaline activity. As a stress hormone, PRL potentiates the antidiuretic activity of Arg-vasopressin [1742] and the AT IIinduced uptake of water and retention of fluids [1743].

Hyperprolactinemia increases the production of androgens [1744] in the adrenal gland, DNA synthesis in the liver [1745], the susceptibility to chemically induced tumors [1746] and spontaneous mammacarcinoma, and the number of estrogen receptors in the mammary gland [1747]. It also prevents stress-induced stomach ulcers [1748], induces hypercalcemia in several species [1749], and reduces the mineral content of the bone [1750].

PRL is also immunostimulatory. Thus, the reactivity of the lymphocytes is reduced by blocking pituitary PRL release with bromocryptin. The immunosuppressive effect of cyclosporin can be abolished by PRL [1731].

7.6.3.3. Placental Lactogen

Placental lactogen (PL) [*9035-54-5*], M_r 22 212 (h-PL), is formed in the placenta in the first trimester of pregnancy and can be detected in the blood and urine of pregnant women. Secretion of PL decreases after birth.

h-PL first stimulates the development of the breast tissue. When the level of h-PL decreases after birth, pituitary h-PRL stimulates the secretion of milk.

h-PL has luteotropic properties: it stimulates the release of progesterone and estrogen from the corpus luteum. This effect is potentiated by h-choriogonadotropin (h-CG). The growth-promoting effect of h-PL is somewhat weaker than that of h-STH, but appears to play a more important role in the development of the fetus.

7.6.4. Somatomedins, Insulin, and Relaxin

Somatomedins of the IGF type (insulin-like growth factors I and II) are structurally related to insulin and relaxin. They are synthesized as single-chain prepropeptides. In the case of insulin and relaxin, three disulfide bridges are formed and the C-peptide (connecting peptide) between the N-terminal B-chain and the C-terminal A-chain is enzymatically removed to give two chains joined together by two disulfide bridges. In the case of IGF-I ($M_r = 7648.8$), and IGF-II ($M_r = 7469.5$), the C-peptide is not cleaved. Relaxin has no influence on the level of glucose but IGF-I, IGF-II, and insulin are functionally related.

7.6.4.1. Somatomedins [1751]

Occurrence. The somatomedins C [*67763-96-6*] and A [*62046-94-0*] (SM-C and SM-A) were previously called the sulfation factor, thymidine factor, nonsuppressible insulin-like activity in serum (NSILA-S), or the multiplication stimulating activity (MSA). The insulin-like growth factor I (IGF-I) is identical to SM-C, SM-A appears to be a deamidated IGF-I [1752]. Somatomedin B [*63774-77-6*] (SM-B) has a completely different structure which is similar to the N-terminal 44 amino acids of vitronectin.

The somatomedins are found in the liver, lungs, prostate, testes, seminal and follicular fluid [1753], thymus, thyroid gland [1754], skeleton, brain, heart, kidneys [1755], gastrointestinal tract, saliva [1756], milk [1757], fibroblasts, chondrocytes [1758], skeletal muscles, and in adipose deposits. A large number of tumors produce the messenger RNA for IGF-I and/or IGF-II [1759].

h-IGF-I, M_r 7649, and h-IGF-II, M_r 7470, each consists of a peptide chain linked with three disulfide bridges. Analogous to proinsulin, the peptide chain is divided into the N-terminal B-chain, the connecting C-peptide, the A-chain, and the C-terminal D-chain. The propeptides also contain the C-terminal E-peptide and the prepropeptides, the N-terminal prepeptide. The structures of IGF-I and IGF-II in various species are described in [1760–1764].

Release. The release of SM is stimulated by growth hormone, prolactin (in the liver [1765]), insulin, injuries [1766], exercise [1767], increased vascular strain [1768], gonadoliberin, follitropin, lutropin, h-choriogonadotropin [1769], estradiol [1770], [1771], ACTH, androgens, parathyroid hormone [1759] and by cAMP (in osteoblast cultures [1772]). Prior to birth, neither IGF-I nor IGF-II appears to be dependent on GH [1773]. Here, placental lactogen, but not GH, insulin, or other growth factors stimulates the synthesis of IGF-II.

SM secretion is reduced by insufficient food intake [1774], low-protein diet [1773], chronic alcohol consumption [1775], and suppression treatment with GnRH agonists [1776].

Serum SM levels fall in patients with hypophyseal insufficiency, diabetes mellitus, and after the age of sixty. Women taking contraceptives and patients with hyperthyroidism have elevated SM levels [1777]. In Cushing's syndrome, the SM level in the spinal fluid is raised [1777].

Receptors [1759]. IGF-I and IGF-II bind with high affinity to specific receptors [1778].

Like the insulin receptor, the IGF-I receptor has two α- and two β-subunits. The α-subunit binds the hormones in the cysteine-rich domain between His^{223} and Met^{274} [1779].

The β-subunit contains tyrosine kinase which phosphorylates intracellular proteins after ligand binding.

The IGF-II receptor is very similar to the mannose 6-phosphate receptor and also binds mannose 6-phosphate [1780]. It consists of a single polypeptide chain, has no kinase activity, does not bind insulin, and binds only poorly to IGF-I.

An IGF binding component found in the serum is the extracellular part of the IGF-II receptor [1781]. In addition, four structurally related IGF binding proteins (IGFBP 1, 2, 3, and 4) have been characterized [1782], [1783]. IGFBP-1 binds IGF-I and IGF-II with similar affinity. IGFBP-2 preferentially binds IGF-II. The majority of serum IGF is bound in a complex consisting of IGF-I or IGF-II (γ-subunit), IGFBP-3 (β-subunit), and an α-subunit that does not bind IGF.

The serum IGF bioactivity is inhibited by h-IGFBP-1 and h-IGFBP-2 [1784], [1785]. In contrast, IGFBP-3 has a stimulating effect on the activity of IGF-I [1759].

Biological Effects. IGF-I stimulates intracellular synthesis of 1,2-diacylglycerol and induces the degradation of phosphatidyl choline, a process which involves protein kinase [1786].

In hypophysectomized animals, administration of IGF-I, like GH, increases body weight and bone growth. GH stimulates the proliferation of osteoblasts via the local synthesis of IGF-I [1787]. The GH-dependent increase in calcitriol after a low-phosphate diet is mediated by IGF-I [1788].

IGF-I and IGF-II bind 100 – 200 times less tightly to insulin receptors than insulin but, like insulin, they increase glucose uptake and oxidation in adipose and muscle tissue. In humans, they have about 6 % of the hypoglycemic activity of insulin [1789] and inhibit endogenous insulin release [1790].

The basal and GHRH-stimulated release of GH is inhibited by a negative feedback mechanism by IGF-I. It acts directly on the pituitary, where it inhibits transcription of the GH gene [1791]. It also releases somatostatin in the hypothalamus [1773]. IGF-II does not have a negative feedback effect on the basal or GHRH-stimulated GH [1751]. IGF-I inhibits the secretion of PRL in the pituitary [1792], but stimulates the release of PRL in cells of the human decidua [1793].

In Leydig cells, IGF-I stimulates the growth of h-CG receptors [1794] as well as the basal and h-CG-stimulated secretion of testosterone [1795]. IGF-I stimulates progesterone synthesis and pregnenolone in ovarian cells [1796].

IGF-I and IGF-II also act as autocrine growth factors in muscle development [1797] and cause proliferation of tumor cells [1798]. They increase the motility of melanoma cells and, therefore, could also increase the metastatic potential [1799].

IGF-I has a modulating effect on the immune system: it stimulates the growth of the thymus [1800], but inhibits the IL-2-induced proliferation and antibody formation of splenocytes in vitro [1801].

Structure – Activity Relationships. The A-chain domains of IGF-I are of importance for receptor binding and the growth effect [1802], the B-chain sequences play a role in the interaction with IGFBPs [1803].

Tyr^{24}, Tyr^{31}, and Tyr^{60} are important for binding of IGF-I to the IGF-I receptor and Tyr^{60} for binding to the IGF-II receptor [1804]. IGF-I-(6 – 70) has only one hundredth of the activity of IGF-I (in stimulating protein synthesis in rat myoblasts), IGF-I-(4 – 70) and IGF-I-(5 – 70) are ten times and twice as active as IGF-I, respectively [1805].

Uses. IGF-I reduces the blood sugar and insulin levels in Mendenhall's syndrome with severe insulin resistance [1806] and in Laron-type dwarfism with a defective GH receptor [1807].

7.6.4.2. Insulin

Occurrence. Insulin [*9004-10-8*], M_r 5808 (h-insulin), was first used in 1921 as a therapeutic agent in diabetes mellitus. It is synthesized in the β-cells of the pancreatic islets of Langerhans. However, immunoreactive insulin has also been found in other tissues (e.g., brain, testes, and liver).

Insulin consists of two peptide chains which are joined together by two disulfide bridges. It is formed from single-chain proinsulin by enzymatic removal of the C-peptide (connecting

peptide) [1808] between the C-terminal A-chain and the N-terminal B-chain. In most species the A-chain (acid chain) contains 21 amino acids, while the B-chain (basic chain) contains 30 amino acids. The C-chain with its N- and C-terminal basic amino acids contains 35 amino acids. In vivo, the C-chain is found without the N- and C-terminal basic amino acids. In physiological concentrations, insulin occurs in human plasma as a monomer which does not bind to serum proteins [1809]. Insulin sequences of various species are given in [1810].

Insulin-like molecules are also observed in the silkworm *Bombys mori* [1811], in the mollusk *Lymnaea stagnalis* [1812], and in the brain of the insect *Locusta migratoria* [1813].

Release [1814]. Insulin is released by an increased plasma level of glucose or amino acids, cAMP, and Ca^{2+} (Mg^{2+}). The plasma insulin level increases after ingestion of food. Incretins are postulated to stimulate the secretion of insulin from the pancreas in a glucose-dependent process. Incretin release from the intestine is increased by oral glucose and inhibited by insulin. The criteria for the postulated incretin are best fulfilled by the glucagon-like peptide 1-(7 – 36)-amide [1815], the glucose-dependent insulinotropic peptide, and oxyntomodulin [1816]. Glucose-dependent secretion of insulin is also stimulated by the gastrin releasing peptide, neurotensin, substance P, gastrin, pentagastrin, CCK-8 (sulfated or unsulfated), the C-terminal tetrapeptide of CCK, cholinergic substances, α_2-adrenoreceptor antagonists [1817], TGF-β_1, TGF-β_2 [1818], oxytocin [1819], ACTH, glucagon, secretin [1820], calcitriol [1821], estradiol [1822], thyroid hormones [1823], prostaglandin D_2, lipoxygenase products [1824], and phospholipase A_2 products [1825].

Low doses of endogenous opioids and exorphins stimulate insulin secretion while high doses have a more inhibitory effect.

The glucose-stimulated release of insulin is inhibited by adrenaline [1826], prostaglandin E_2 [1827], somatostatin, pancreastatin, pancreatic peptide, galanine [1828], calcitonin gene related peptide [1829], amylin, calcitonin, exogenous insulin [1830], growth hormone, interferon [1831], interleukin 1β, and interleukin 6 [1832].

The cell-specific destruction of the pancreatic β-cells, which precedes insulin-dependent diabetes mellitus occurs by an autoimmune mechanism. Autoantibodies have been found in more than 80 % of newly diagnosed patients. The target of the autoantibodies is a β-cell autoantigen which has been identified as glutamic acid decarboxylase [1833] or as heat shock protein 65 [1834].

Receptors [1835]. The insulin receptor consists of two α- and two β- subunits joined together by disulfide bridges to give the configuration: (β-chain-S-S-α-chain)-S-S-(α-chain-S-S-β-chain). The cysteine-rich domain between Asn^{230} and Ile^{285} of the α-chain is important for insulin binding [1836]. The β-subunit is a transmembrane protein and contains a tyrosine-specific protein kinase. Insulin stimulates phosphorylation of the β-subunit. Autophosphorylation of the insulin receptor is restricted by triiodothyronine [1837].

The receptor is synthesized in the form of a prepropeptide.

Diabetes, resistance to insulin, can result from receptor defects (e.g., a deletion in the tyrosine kinase domain [1838] or the subtitution of valine for Gly^{996} [1839]). Trp^{1200} is also important for the normal function of insulin receptor kinase [1840]. In Hodgkin's disease, antibodies against the insulin receptors can cause hypoglycemia because of their insulin-like activity [1841].

The formation of insulin receptors is stimulated by glucose [1842] and down regulated by insulin and proinsulin [1843]. In cancerous breast tissue, the concentration of insulin receptors is more than six times that in normal tissue and correlates with the size of the tumor and with the estrogen receptor concentration [1844].

The following positions in insulin appear to be important for receptor binding: A-chain: Gly^1, Gln^5, Tyr^{19}, and Asn^{21}; B-chain: Val^{12}, Tyr^{16}, Arg^{22}, Gly^{23}, Phe^{24}, Phe^{25}, and Tyr^{26}.

Estrogen, progesterone [1845], h-GH, h-GH-(7 – 13) [1846], and relaxin [1847] increase the binding of insulin to the receptor; prolactin [1847], heparin [1848], or contraceptive therapy in women [1849] reduces binding.

Biological Effects. Insulin lowers blood glucose by promoting glucose uptake in skeletal muscle, heart, and adipose tissue, by activating glycogen synthesis [1850], and by inhibiting glycogenolysis in the liver [1851]. Glucose transport proteins are involved in the uptake of glucose [1852]. Taurine [1853], the basic peptides Arg-Lys and Arg-Arg [1854], and somatostatin potentiate the insulin effect on the blood glucose level.

Apart from stimulating glucose and amino acid transport, insulin also increases the secretion of somatomedins, the affinity of the IGF-II receptors [1855], the proliferation and differentiation of cells (healing of wounds), ion transport, renal Na^+/K^+ ATPase [1856], lipogenesis, potentiates the FSH-stimulated synthesis of estrogen and progestin [1857] and the h-CG-stimulated synthesis of testosterone [1858], increases food intake [1859], stimulates the secretion of gastric acid [1860] and bile flow, and is important for postprandial cholecystokinin- or secretin-stimulated exocrine pancreatic secretion [1861].

Hypoglycemia induced by insulin is a stress reaction which leads to the release of ACTH and cortisol [1862]. Insulin also increases the K^+-stimulated production of aldosterone [1863]. In type I diabetics, insulin lowers the level of cortisol raised by fasting [1864].

Insulin inhibits the synthesis and release of somatostatins and enteroglucagon [1865], reduces the basal and PTH-stimulated excretion of phosphate in the urine [1866] as well as renal Ca^{2+} reabsorption, stimulates the synthesis of collagen [1867], and potentiates the PTH-stimulated synthesis of calcitriol in the kidney [1868].

Insulin inhibits the noradrenaline- or AT II-stimulated contraction of arteries and veins (hypotensive effect [1869]), increases the heart rate [1870], and is positively inotropic [1871].

The inability of a given concentration of insulin to produce an expected biological effect is called insulin resistance. This resistance can be caused by circulating antagonists of insulin activity (antibodies, prostaglandins, and glucocorticoids [1872]), down regulation of the receptors, or receptor defects.

Structure – Activity Relationships. The biological activity of insulin is expressed in international units (IU). The activity is measured in the mouse cramp test or by determining the decrease in the blood sugar level in the rabbit. Crystalline insulin contains 26 – 28 IU/mg.

proinsulin is only about one-third as active as insulin in lowering the blood sugar level, but its action is significantly prolonged [1873]. The antilipolytic activity of h-proinsulin is higher than that of h-insulin [1874].

hydrophobic interactions are responsible for the formation of insulin dimers. The hexamer of insulin is formed from three dimers with two or four zinc atoms [1875]. Monomeric insulin is assumed to be the biologically active form, i.e., binds to the receptor. The regions around A1, A2, A19, A21, and b22 – B25 are important for biological activity.

fully active insulin is obtained when the B-chain is shortened at the N-terminus by two amino acids and at the C-terminus by three amino acids.

[aspb^{10}]h-insulin [1876] and de-(b^{26}–B^{30})-[AspB^{10}, tyr-nh$_2$B^{25}]insulin [1877] are more active than h-insulin. GlyB^{23} can be replaced by D-Ala without loss of activity, but [alab^{23}]insulin has a greatly reduced biological activity [1878]. Both [D-PheB^{24}]b-insulin and [D-AlaB^{24}]b-insulin still possess activity [1879]. Substitution of Glu for TyrB^{26} or thrb^{27} or of Asp for ProB^{28} leads to monomeric analogues having a slightly higher activity [1880]. ThrB^{29} can be replaced by many different amino acids and still retain activity [1881].

the n-terminal Gly of the A-chain can only be replaced by D-amino acids without loss of activity. [D-LeuA^1]insulin possesses full insulin activity and [D-TrpA^1]insulin is even slightly more potent than native insulin. The hydroxyl group of tyra^{19} forms a hydrogen bond with the carboxyl group of glya^1 and stabilizes the molecule. Modifications of asna^{21} lead to less active compounds. The cysteines are exremely important for the tertiary structure.

less soluble analogues with prolonged activity are obtained by introducing Arg into the molecule [1882–1884], amidating the Glu-γ-

carboxyl groups and the C-terminus of the B-chain [1885], and by the palmitoylation of the a-chain [1886]. Long-acting analogues include [glya^{21},ArgB^{27},ThrB^{30}-amide]h-insulin (NovoSol-Basal) [1882]. [aspb^{9},GluB^{27}]h-insulin [1887] and [aspb^{10}]h-insulin [1887] are monomeric derivatives that act especially quickly.

Uses [1888], [1889]. Many insulin preparations are available for the parenteral treatment of diabetes mellitus. Bovine, porcine, and human insulin are generally used. commercially available h-insulin preparations are either enzymatically modified p-insulin [H-Insulin, Depot-H-Insulin, Komb-H-Insulin (Hoechst); Insulin Monotard hm, Insulin Actrapid hm (novo); Insulin velasulin Human, Insulin mixtard Human (Nordisk)] or chain recombinant insulin produced by genetic engineering in bacteria (Huminsulin, Eli Lilly). In enzymatically modified products the C-terminal alanine of p-insulin is substituted by a threonine ester with the aid of trypsin. the ester function is then hydrolyzed to give h-insulin. In chain recombinant h-insulin, the A- and B-chains are synthesized separately and subsequently linked by oxidation, see also → Genetic Engineering.

de-pheb^{1}-insulin derivatives (Insulin Defalan, hoechst) have full insulin activity, but are more soluble and less antigenic than insulin. In patients with insulin allergy, de-pheb^{1}-p-insulin has been used successfully because it has a low antigenicity [1890]. However, de-Phe-insulins are no longer on the market.

insulin pumps have been developed for better insulin adjustment, pulsatile infusion appears to be more efficient than continuous infusion [1891].

treatment with insulin is also recommended in total parenteral feeding [1892], in cancer-induced anorexia, and loss of weight [1893]. Topically applied insulin promotes the healing of wounds [1894].

7.6.4.3. Relaxin [1895]

Occurrence. Relaxin (RLX) [*9002-69-1*], M_r 6333 (h-RLX 2), is found primarily in the serum and tissues of pregnant mammals. It occurs in especially high concentrations in the corpus luteum of pregnant animals, and is isolated from this source. In addition, RLX is found in the endometrium during pregnancy, breast [1896], testes, prostate, and seminal fluid.

RLX, like insulin, consists of an A- (24 amino acids in humans) and a B-chain (32 amino acids in humans) linked by sulfide bridges and is synthesized as a single-chain prohormone. h-RLX occurs in two forms, h-RLX-2 is formed in the ovaries during pregnancy [1897]. p-RLX occurs in three forms. RLX sequences from various species are described in [1897].

h-Relaxin-2

```
*QLYSALANKCCHVGCTKRSLARFC
  SWMEEVIKLCGRELVRAQIAICGMSTWSKRSL
```

Release. The plasma level of RLX increases greatly at the end of pregnancy and falls rapidly after birth. In hypophysectomized animals, endogenous RLX can be activated by estrogens and progesterone. the release of RLX is increased by h-CG [1898], oxytocin, and prostaglandin F_2. Indomethacin prevents the increase in the RLX level and delays birth.

In trophoblastic disease, which is accompanied by an increase in the plasma h-CG level, RLX is detectable in the plasma [1899].

Biological Effects. Purified RLX (NIH standard, RXN-P1) has about 3000 U/mg. One unit is the threshold dose which causes a softening of the interpubic disc in two-thirds of the guinea pigs tested.

In advanced pregnancy, RLX reduces the contraction of the uterus. This effect is supported by progesterone and is important for the maintenance of pregnancy. RLX has a growth-promoting and relaxing effect on the uterus and cervix and a growth-promoting and lactation-inhibiting effect on the mammary gland. RLX alone inhibits progesterone synthesis, but increases estrogen synthesis [1900]. RLX also appears to prepare the myometrium for parturition because without it oxytocin cannot induce birth. RLX inhibits prostaglandin synthesis during pregnancy, but stimulates it during birth [1901].

The relaxing effect of RLX on the interpubic disc (pelvic symphysis) occurs because the compact cartilaginous tissue between the two pubic bones is converted to a more flexible structure. the water content of the tissue is increased and the secretion of proteolytic enzymes is stimulated, loosening the network of collagen and glycosaminoglycan [1902]. Estrogen and hypophyseal hormones (e.g., growth hormone) are also involved in this deaggregation of collagen. Intravaginal RLX (2 mg/patient) causes cervical maturation in humans and induces birth.

RLX increases sperm motility and exerts a hypotensive effect [1903]. It inhibits the pressor activity of angiotensin II, vasopressin, and noradrenaline [1904].

Structure – Activity Relationships. The shortening of the A-chain of p-RLX by two amino acids at the N-terminus does not affect biological activity, whereas deletion of five or six amino acids halves the biological activity [1905].

Oxidation of $TrpB^{27}$ in p-RLX with *N*-bromosuccinimide has no influence on biological activity. However, p-RLX becomes inactive when $TrpB^{18}$ is oxidized.

7.6.5. Somatostatin [1906]

Occurrence. Somatostatin [*38916-34-6*], also called somatotropin release inhibiting hormone or factor (SRIH or SRIF), M_r 1638, is formed as prepro-SRIH. The main product of gene expression in the stomach and pancreas of mammals is pro-SRIH-(1 – 64), which is cleaved at the C-terminus to form SRIH-28 with 28 amino acids and SRIH-14 with 14 amino acids [1907].

SRIH-14 and SRIH-like substances have been found in the hypothalamus, nervous system, pancreatic islet D-cells, gastrointestinal mucosa, thymus, extrahepatic bile ducts, plasma [1908], in the C-cells of the thyroid gland, ovaries, and in plants (e.g., spinach [1909]). Somatostatin sequences of various species are described in [1910].

Release. SRIH is released in the antrum (lower part of the stomach) in response to fasting [1911], acid in the antrum, intraduodenal infusion of fat and HCl [1908], stress [1912], cholinergic and β-adrenergic mechanisms, dopamine D_2 agonists [1913], estrogen and androgens [1913], and numerous peptide hormones including growth hormone releasing hormone and somatomedins [1908], [1914–1917].

The secretion of SRIH is reduced shortly after meals [1911], by electrical stimulation of the vagus, sham feeding, α-adrenergic stimuli, serotonin [1918], and various peptides (e.g., endogenous opioids, galanine, pancreatic peptide, and insulin).

The plasma level of SRIH is lower at night [1919]. The plasma SRIH level in children below the age of two is raised. Above two years its level is normal and increases continuously with age [1920].

The plasma SRIH level is increased in patients with chronic renal failure, cirrhosis [1921], and primary hypothyroidism [1922]. The level of SRIH is raised in the cerebrospinal fluid of patients with brain tumors, metabolic encephalopathy, spinal cord compression, and intracranial hypertension [1923].

The plasma level of SRIH is reduced in patients with pernicious anemia, achlorhydria [1920], cluster headache [1924], psoriasis [1925], obesity [1926], and in women who are taking estrogen-containing contraceptives [1927]. The level of SRIH in the cerebrospinal fluid is reduced in patients with Alzheimer's disease [1928], unipolar depression, and active multiple sclerosis [1912]. The level of SRIH is reduced in the cortex and hippocampus of patients suffering from Parkinson's disease [1929].

Receptors. Several SRIH types of receptors are found in the brain.

SRIH receptors are detected in most GH- and TSH-producing pituitary adenomas, carcinoids, islet cell carcinomas, EGF-receptor-negative glial tumors, and small cell lung carcinomas [1930]. The number of SRIH receptors is reduced in the cerebral cortex of patients with Alzheimer's disease [1931].

Biological Effects. SRIH-14 [1932] stimulates phosphodiesterase, inhibits cAMP synthesis, blocks calcium influx, and the turnover of phosphoinositides in the cytosol [1933]. It also inhibits the release and action of hormones (e.g.,

growth hormone (GH), prolactin, thyrotropin, stress-induced corticotropin [1934]), calcitonin, insulin, glucagon, GIP, VIP, secretin, pancreatic polypeptide, gastrin releasing peptide [1908], gastrin, cholecystokinin, and motilin. GH is the most sensitive to SRIH inhibition, followed by thyrotropin [1935].

SRIH inhibits exocrine secretion of gastric acid, pepsin (anti-ulcer effect), pancreatic enzymes, pancreatic bicarbonate, colonic fluid (reduction of secretory diarrhoea [1936]), bile flow (patients with somatostatinoma usually have gall-stones [1937]). It also potentiates human platelet aggregation stimulated by collagen and arachidonic acid [1938] (control of upper gastrointestinal hemorrhage).

SRIH enhances gastric emptying [1939] and intestinal transit [1940]. It may be useful in the management of the dumping syndrome [1941]. SRIH inhibits cell proliferation in the exocrine pancreas [1942], rabbit jejunum [1943], liver after hepatectomy [1944], and tumor growth. The antitumor effect of SRIH is mediated by the stimulation of a tyrosine phosphatase [1945].

Immunomodulatory actions include increase of leukocyte migration inhibitory factor [1946], enhancement of human lymphocyte natural killer activity [1947], and mouse spleen lymphocyte proliferation [1948].

Structure – Activity Relationships. The substitution of D-Trp for Trp^8 produces an analogue that has 8 times the activity of SRIH in inhibiting GH release.

Potent, long-acting SRIH analogues of the urotensin II type are of tremendous interest [1949–1952]. For instance, octreotide [*49474-41-2*], [*79517-01-4*] is 70 times more effective than SRIH-14 in inhibiting GH. It has a long duration of action when given intramuscularly [1949].

Cyclic peptides without a disulfide structure are also potent, long-acting compounds. Examples are cyclo-(*N*-Me-Ala-Tyr-D-Trp-Lys-Val-Phe) (seglitide) and cyclo-(Pro-Phe-D-Trp-Lys-Thr-Phe).

Cyclic retropeptides of the latter, e.g., cyclo-(Phe-Thr-Lys-Trp-Phe-D-Pro), inhibit the uptake of cholate and phallotoxin in liver cells [1953] and protect against taurocholate- and ceruletide-induced pancreatitis [1954], and against ethanol-induced stomach lesions [1955], without possessing true SRIH activity.

Analogues of octreotide which usually contain penicillamine instead of Cys^7 are poor ligands for SRIH receptors, but exhibit stronger binding to opioid receptors [1956]. They act as selective antagonists for μ-opioid receptors, i.e., they inhibit morphine induced analgesia [1957].

Uses. SRIH-14 infusions (Stilamin, Serono; Aminopon, UCB; Somatostatin Ferring, Ferring; Somatostatin Labaz, Sanofi) have proved useful for the treatment of bleeding peptic ulcers and gastrointestinal lesions, for preventive treatment against stress-induced ulcers, and in the healing of fistulae of the small intestine and gallbladder.

Octreotide (Sandostatin, Sandoz) [1958] is used in the treatment of GH- and thyrotropinsecreting pituitary tumors, carcinoid tumors, glucagonomas, insulinomas, and gastrinomas. The use of octreotide in acute esophageal variceal bleeding, pancreatic pseudocysts, external gastrointestinal and pancreatic fistulae, short bowel syndrome, dumping syndrome, and refractory hypersecretory diarrhoea related to the acquired immunodeficiency syndrome has provided encouraging results. Preliminary reports indicate the efficiency of octreotide in the treatment of psoriasis, autonomic neuropathy [1959] and of carcinoid flush [1960], and its ability to reduce growth in tall adolescents. Other potential applications include the control of pain [1961], rheumatoid arthritis, and diabetic microangiopathy as well as the prevention of postoperative pancreatic complications (fistulae, pancreatitis, and abscess).

7.6.6. Pancreastatin

Occurrence. Pancreastatin (PST) [*117148-67-1*] from the pancreas of the pig contains 49 amino acids [1962]. Sequences from

other species are given in [1963]. h-PST contains 52 amino acids, M_r 5509.

The precursor of pancreastatin is chromogranin A, an acidic glycoprotein which is widely distributed in the neuroendocrine system and released in large amounts from the chromaffin cells of the adrenal medulla [1963]. Pancreastatin contains the penta-Glu sequence of gastrin (GT) and has a C-terminus that is similar to that of gonadoliberin (GnRH).

In patients with non-insulin-dependent diabetes mellitus, the plasma pancreastatin level increases after the digestion of glucose, which is not the case in healthy persons [1964].

Biological Effects. Pancreastatin inhibits the first phase of glucose- or arginine-induced release of insulin and the arginine-induced release of somatostatin, but potentiates the arginine-induced secretion of glucagon [1965] from the rat pancreas. These changes are reminiscent of non-insulin-dependent diabetes.

In the rat, pancreastatin lowers the plasma insulin level and increases the plasma level of glucose in response to intragastric glucose [1966] and raises the plasma glucagon level in response to intravenous arginine [1967]. Like glucagon, it stimulates hepatic glycogenolysis [1968].

Pancreastatin also inhibits the CCK-stimulated secretion of protein and fluid from the pancreas [1967] and the CCK-stimulated growth of human pancreatic adenocarcinoma [1969].

Structure – Activity Relationships. The inhibitory effect on the glucose-stimulated release of insulin is restricted to the C-terminal region of the molecule [1962]. The shortest, active C-terminal fragment is p-PST (35 – 49) [1970]. The C-terminal amide function is required for biological activity [1970].

8. Neurotensin [1971]

Occurrence. Neurotensin (NT) [*39379-15-2*], M_r 1673 (h-NT), contains 13 amino acids and was first isolated from bovine hypothalamic extracts. Immunoreactive NT was later found in the gastrointestinal tract. The structurally and functionally related hexapeptide p-neuromedin N was isolated from the porcine spinal cord [1972]. NT and neuromedin N are coded on the same gene. Preprohormones from the rat, cow, and dog have also been characterized [1973].

h-Neurotensin	*Q L Y E N K P R R P Y I L
p-Neuromedin N	K I P Y I L

In humans, immunoreactive NT has been isolated primarily from the hypothalamus, median eminence, substantia nigra, and brain stem structures. It occurs with dopamine in dopaminergic neurons [1974]. NT and its main metabolite NT-(1 – 8) are also found in the adrenal medulla [1975].

The level of immunoreactive NT is raised by about 250 % in hot flushes experienced during menopause, but this material is not identical to NT or one of its known metabolites.

Release. NT is released from hypothalamic preparations by depolarizing K^+ and dopaminergic mechanisms. Methamphetamine, dopamine [1976], the dopamine antagonist haloperidol [1977], and neuroleptic agents [1978] release NT in the brain and increase the number of NT-containing neurons.

NT is released from the N-cells of the small intestine (particularly the ileum) into the blood in response to meals rich in fat and oleic acid, bombesin infusions, adrenaline [1979], hydrocortisone [1980], nerve growth factor, and insulin [1980]. Secretion of NT from the intestine is inhibited by somatostatin (SRIH) [1981] and dexamethasone [1982].

The level of NT may be elevated in tumor patients [1983][1984][1985]. The spinal fluid of children suffering from febrile aseptic meningitis has a low content of immunoreactive NT [1986].

Biological Effects. NT and C-terminal fragments such as NT-(8 – 13) raise the levels of cytosolic calcium [1987] and cGMP [1988] and stimulate the formation of inositol phosphates [1989].

NT has neuroleptic properties when applied centrally. It reduces dopamine synthesis within the nerve ends, increases the turnover of dopamine [1990], and inhibits the hyperactivity of dopamine receptor agonists [1991].

When centrally applied, NT stimulates the release of SRIH, luteotropin [1992], and corticosterone [1993]. It also enhances the effect of barbiturates [1985], exerts an antinociceptive effect [1994], reduces the secretion of thyrotropin, growth hormone, and prolactin, inhibits the carbachol, 2-deoxy-D-glucose and pentagastrin-stimulated gastric acid secretion [1995], exerts a cytoprotective effect on stress-induced gastric ulcers, and has a hypothermic effect [1996].

The most sensitive target organs for intravenously applied NT are the upper gastrointestinal tract and adipose tissue [1997]. NT reduces sphincter tone, inhibits gastric secretion, gastric emptying, and intestinal motility. It has a vasoconstrictive effect in adipose tissue.

In the stomach, NT inhibits the pentagastrin-stimulated release of pepsin and gastric acid secretion. It increases the exocrine $NaHCO_3$ secretion in the pancreas and the endocrine secretion of pancreatic peptide, insulin, and glucagon.

Relatively high doses of NT (> 100 ng kg^{-1} min^{-1}) raise the plasma glucose concentration and reduce blood pressure, probably through the release of histamine and other vasoactive substances from mast cells. In concentrations of $10^{-11} - 10^{-7}$ mol/L, NT enhances phagocytosis of macrophages and neutrophils and, consequently, could play a role in inflammatory processes.

Structure – Activity Relationships. [Gln^4]NT, g-NT, and [monoiodo-Tyr^3]NT [1998] appear to be identical to b-NT with respect to biological activity (hypotensive and hyperglycemic assays in the rat, radioimmunoassay). In vitro the C-terminal hexapeptide NT-(8 – 13) has almost the same activity as the entire molecule. The C-terminal pentapeptide and the carboxyl group are essential for activity. The C-terminal carboxyl group is not required for the hypotensive, vasodilating activity because cyclopeptides are potent hypotensive agents [1999].

The entire molecule appears to be required for the inhibition of the pentagastrin-stimulated secretion of gastric acid and pepsin and for the motility-inhibiting effect.

NT-(8 – 13) has the same central antinociceptive effect as NT. However, even shorter sequences such as NT-(9 – 11), NT-(8 – 10), or NT-(8 – 11)NH-C_2H_5 exhibit this activity [2000].

The cytoprotective activity of intracerebroventricularly applied NTs depends on the N-terminal sequence. NT-(8 – 13) and NT-(1 – 6) do not have cytoprotective activity, whereas NT-(1 – 8) and NT-(1 – 10) exhibit significant cytoprotection [2001].

The central hypothermic activity is especially pronounced in [D-Tyr^{11}]NT and [dopa^{11}]NT. [D-Tyr^{11}]NT also inhibits the hyperactivity induced by dopamine agonists when applied centrally [2002].

Depending on the dose, the NT-induced histamine-release, hypotensive effect [2003], synthesis of inositol phosphate [2004], and secretion of glucagon can be inhibited by [D-Trp^{11}]NT.

9. Motilin [2005]

Occurrence. p-Motilin (MT) [*9072-41-7*], M_r 2699.1 (h-MT), is a peptide containing 22 amino acids. The precursor of h-MT has been characterized via the cDNA [2006].

Motilin is found primarily in the jejunum but immunoreactive motilin has also been found in the mucosa of the esophagus, stomach, duodenum, ileum, and colon, in the pancreas, kidneys, adrenals, gallbladder, and brain.

Erythromycin A [2007] and the erythromycin derivative EM-523 [2008] are macrolide antibiotics which greatly increase the gastrointestinal motor activity and are motilin receptor agonists.

Release. The release of motilin is stimulated by oral fat, exogenous and endogenous bile acids, bombesin, alkalization of the duodenum (in the dog), acidification of the duodenum (in humans and pigs), stimulation of the vagus, exogenous motilin, and atropine [2009].

Release is inhibited by oral glucose, insulin, somatostatin, pancreatic peptide, VIP, and by sham feeding [2010].

In humans, elevated levels of MT have been observed in diarrhoea, kidney failure, after abdominal surgery and in alcoholics who do not have liver disease [2011].

Biological Effects. Motilin increases smooth muscle Ca^{2+} transport and stimulates intracellular cGMP synthesis. On a molar basis,

motilin has 50 times the contracting effect of acetylcholine in the duodenum.

The motilins appear to be species specific [2012]. Motilin induces contraction of the gastrointestinal tract and accelerates gastric emptying and intestinal transit. MT also contracts the lower esophageal sphincter and the gallbladder, and activates the Oddi sphincter [2013]. The cyclic pancreatic secretion of water, bicarbonate, and protein is increased by MT [2014].

In fasting rats, intraperitoneally applied MT (5 – 10 µg/kg) increases food uptake. This effect can be abolished by naloxone or pentagastrin. Thus, MT appears to be responsible for hunger during fasting [2015]. An infusion of low doses of motilin accelerates the absorption of glucose, increasing the plasma levels of glucose, GIP, and insulin. An infusion of high doses of motilin has the opposite effect.

Structure – Activity Relationships p-MT-(1 – 16) has 3 % of the p-MT activity (contraction of duodenum). Gly^8 can be replaced by D-Ala without loss of activity (i.e., contraction of the duodenum); Met^{13}, Gln^{14}, and Glu^{15} do not appear to be important for biological activity [2016], whereas substitution of Ser or Lys for Phe^1 produces compounds that are 250 and 1000 times less active, respectively [2017].

10. Pancreatic Spasmolytic Peptide

Occurrence. Pancreatic spasmolytic peptide (PSP) [*82987-77-7*], M_r 11 711, is a pyroglutamyl peptide containing 106 amino acids and seven disulfide bridges [2018]. Immunoreactive PSP is found in low concentrations in many organs, but substantial amounts only occur in the pancreas. There is about 50 % sequence homology between p-PSP-(14 – 49) and p-PSP-(63 – 98). There is great similarity between the sequences of p-PSP and the protein pS_2 which was isolated from human gastric juice [2019] and is induced by estrogen in the human breast cancer cell line MCF-7 [2020]. pS_2 is identical to the human epidermal growth factor-like immunoreactive factor [2021]. A protein from the skin gland of *Xenopus laevis*, known as the APEG protein [2022], has a sequence at its C-terminus that is very similar to p-PSP and h-pS_2. Another protein from *Xenopus laevis*, which was characterized via the cDNA structure, contains, after possible processing, two basic sequences (spasmolysin I and spasmolysin II) that are very similar to PSP [2023].

Biological Effects. p-PSP inhibits the activity of adenylate cyclase in the intestinal mucosal cell membranes of the rat [2024]. It inhibits gastrointestinal motility and the secretion of gastric acid in laboratory animals after parenteral and oral application. It also reduces the pressure and the wave frequency of the Oddi sphincter [2025]. PSP acts like a growth factor on MCF-7 cells [2019].

1. Introduction

Peptides are chains of amino acids linked together by amide bonds. Peptides with up to ten amino acids are generally termed *oligopeptides* ($M_r \leq$ ca. 1000). *Polypeptides* contain 10 – 100 amino acids (M_r ca. 1000 – 10 000). *Proteins* contain > 100 amino acids ($M_r > 10\,000$).

Peptides have a broad range of applications, particularly in diagnostic and therapeutic areas, because they play important roles in the regulation and maintenance of biological processes. Demand for these products is already considerable and will probably increase dramatically in the future. Peptides may be synthesized by both chemical and biotechnological methods. Much of the emphasis in the field has been directed toward the development of methods for the synthesis and purification of peptides in high yield and in the most rapid and economical way.

2. Fundamentals of Peptide Synthesis [1–8]

Peptides are formed by the condensation of α-amino acids as in the following general reaction:

Since amino acids contain at least two functional groups (the α-amino and α-carboxyl groups), certain precautions must be taken to obtain a well-defined peptide. Thus, the amino group of one amino acid and the carboxyl group of the other must be blocked or "protected" to prevent undesirable side reactions. For the same reason, other functional groups in the amino acid side chains (R^1 and R^2) should also be protected.

The protecting groups used for side-chain functional groups must be stable during the procedures which are used to form the peptide bonds in the chain. Conversely, the protecting groups used for the α-amino and α-carboxyl groups must be more temporary in nature, so that they can be removed without cleaving the groups protecting the side chains. Only if these conditions are met can the α-amino and α-carboxyl groups react unequivocally in the condensation step. Once assembly of the peptide has been com-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a19_157

pleted, all of the protecting groups must be removed without significant damage to the final, desired peptide.

Formation of the peptide bond requires activation of one of the two functional groups, generally the carboxyl group. Activation is usually accomplished by conversion to a reactive species, in which the carboxyl group is susceptible to nucleophilic attack by the amine group of the second amino acid residue.

All α-amino acids except glycine have at least one asymmetric center – the α-carbon atom. Peptides and proteins isolated from natural sources almost always contain amino acids of the L- configuration. Unfortunately, racemization can occur during the activation step, the extent depending on the nature of the amino acid side chain and the protecting groups used. Thus the suppression of racemization is an extremely important concern in planning the synthesis of a peptide.

3. Protecting Groups

An enormous variety of protecting groups have been developed to solve particular problems arising during peptide synthesis. However, of these, only a relatively small number are currently in use.

3.1. Amine Protecting Groups

Some amine protecting groups are listed in Table 1 (see also [1–3]). The most important are the *tert*-butoxycarbonyl (Boc), benzyloxycarbonyl (Z), and fluorenylmethoxycarbonyl (Fmoc) groups. These groups are cleaved under a wide variety of conditions thus allowing a very broad range of applications.

The development of the *Z protecting group* by ZERVAS and BERGMANN in 1932 [9] was a milestone in peptide chemistry. Z-Protected amino acid derivatives are prepared by the Schotten–Baumann reaction:

Nowadays the Z group is introduced by using *N*-(benzyloxycarbonyloxy)succinimide [*13139-17-8*], because the formation of oligopeptides can then be avoided. The protecting group may be removed either by hydrogenation or under anhydrous, strongly acidic conditions (e.g., with hydrobromic acid in acetic acid), giving innocuous byproducts which are removed easily:

Boc-amino acids were originally prepared by the treatment of amino acids with *tert*-butyl azidoformate. However, this reagent is no longer available commercially and has been replaced by *tert*-butyl dicarbonate [*24424-99-5*] (**1**):

The Boc group is cleaved under acidic conditions, most commonly with trifluoroacetic acid (TFA).

Attempts to prepare *Fmoc-amino acid derivatives* using 9-fluorenylmethyl chlorocarbonate [*28920-43-6*] often lead to the formation of substantial amounts of Fmoc-oligopeptides [10]. However, this side reaction may be avoided by using Fmoc-succinimidyl carbonate [*82911-69-1*], the reagent of choice today.

Removal of the Fmoc group is accomplished by base-catalyzed elimination:

Table 1. Amine protecting groups

Protecting group (abbreviation)	Structure	Cleavage agents	Stability
Trifluoroacetyl (TFA)	F_3C-CO-	base	acids, H_2/Pd
Phthaloyl (Pht)		hydrazine	H_2/Pd, CF_3COOH
Dithiasuccinoyl (Dts)	$S-CO-$ $S-CO-$	thiols	H_2/Pd
Benzyloxycarbonyl (Z)		H_2/Pd, HBr/CH_3COOH	CF_3COOH, base
4-Methoxybenzyloxycarbonyl (Moz)		CF_3COOH, H_2/Pd	base
4-Dihydroxyboronatobenzyloxy-carbonyl (Dobz)		H_2/Pd, H_2O_2, HBr/CH_3COOH	CF_3COOH, base
tert-Butoxycarbonyl (Boc)	$(H_3C)_3C-O-CO-$	CF_3COOH	H_2/Pd, base
9-Fluorenylmethoxycarbonyl (Fmoc)		base, H_2/Pd	acids
2-(3,5-Dimethyloxyphenyl)propyl-2-oxycarbonyl (Ddz)		5% CF_3COOH, CH_2Cl_2, $h\nu$	H_2/Pd, base
2-Nitrophenylsulfenyl (Nps)		weak acids	
Trityl (Trt)		H_2/Pd, acids	base

The Fmoc group has become increasingly popular in solid-phase peptide synthesis because of its facile removal under so-called "orthogonal" conditions (i.e., those under which sidechain protecting groups are completely stable).

The incorporation of lysine into the growing peptide chain requires the protection of both the α-amino group and the ε-amino group of the side chain. In most cases, two different protecting groups are required. The most widely used combinations are Boc-Lys (2-Cl-Z)-OH [*54613-99-9*] (**2**), Z-Lys (Boc)-OH [*2389-60-8*] (**3**), and Fmoc-Lys (Boc)-OH [*71989-26-9*] (**4**).

4

The 2-chlorobenzyloxycarbonyl (2-Cl-Z) group is an example of a more acid-stable ε-amine protecting group. Such groups are more stable to the acid conditions used for cleavage of the Boc group in solid-phase synthesis and are only cleaved by hydrogen fluoride.

3.2. Carboxyl Protecting Groups [1–3]

Some of the wide variety of available carboxyl protecting groups are listed in Table 2. Although, in principle, peptide synthesis can be carried out without protecting the carboxyl group(s) of the amine component, protection of these groups is advisable in most cases.

Simple alkyl esters (e.g., methyl and ethyl esters) may be prepared by the Fischer esterification method (refluxing the amino acid in the alcohol saturated with hydrogen chloride). An alternative method involves the addition of thionyl chloride to the cold alcohol, followed by addition of the amino acid. For other preparations see [2] and literature cited therein. The protecting groups are removed by saponification; complications can occur with longer peptides because saponification may be incomplete and racemization may occur. *Benzyl and 4-nitrobenzyl esters* are also cleaved by hydrogenation, which is an attractive advantage compared with alkyl esters. Benzyl esters may be prepared by reaction of amino acids with benzyl alcohol in the presence of an acidic catalyst, such as hydrogen chloride or 4-toluene sulfonic acid:

Another very important protection method is formation of the *tert-butyl ester,* which is especially useful when used in combination with the Fmoc and Z protecting groups. It is most widely used for protection of the acidic side chains of aspartic acid and glutamic acid. *tert*-Butyl esters are resistant to nucleophiles and are unaffected by treatment with base or hydrogenation. They may be prepared by acid-catalyzed addition of isobutene:

Cleavage of *tert*-butyl esters is accomplished under similar conditions to removal of the Boc group, i.e., by treatment with anhydrous acids, such as trifluoroacetic acid, HCl, or HBr in organic solvents.

3.3. Sulfhydryl Protecting Groups [1–3]

The sulfhydryl side chain of cysteine must be protected because of problems encountered with its nucleophilicity and also the possibility of its oxidation to disulfides. Sulfhydryl protecting groups are listed in Table 3. Preferred protecting groups are the benzyl (Bzl), trityl (Trt), and acetamidomethyl (Acm) groups. The trityl and acetamidomethyl groups can be removed under relatively mild conditions (i.e., with mercuric ions at pH 4, or with iodine). The trityl group is also removed by acid and may be selectively oxidized with iodine in the presence of the acetamidomethyl group. On the other hand, the acetamidomethyl group is stable to hydrogen fluoride, which cleaves the benzyl group. Substituted benzyl groups (e.g., 4-methyl- or 4-methoxybenzyl groups) are used widely in solid-phase synthesis. Peptides containing more than one disulfide bond require selectively cleavable sulfur protecting groups to ensure the correct

Table 2. Carboxyl protecting groups

Protecting group (abbreviation)	Structure*	Cleavage agents	Stability
Methyl ester (OMe)	$H_3C-O-CO-$	base	acids, H_2/Pd
tert-Butyl ester (OtBu)	$(H_3C)_3C-O-CO-$	CF_3COOH	base, H_2/Pd
Benzyl ester (OBzl)		H_2/Pd, base	CF_3COOH
4-Nitrobenzyl ester (ONb)		H_2/Pd, base	CF_3COOH, HBr/CH_3COOH

∗ After peptide synthesis the ester is cleaved to form the relevant alcohol and amino acid carboxyl group.

Table 3. Sulfhydryl protecting groups

Protecting group (abbreviation)	Structure	Cleavage agents	Stability
Benzyl (Bzl)		HF, Na/NH_3	acids, iodine
4-Methoxybenzyl (Mob)		HF, Na/NH_3	CF_3COOH, iodine
Acetamidomethyl (Acm)	$H_3C-CONH-CH_2-$	iodine, Hg^{2+}	HF, base
S-tert-Butylthio (StBu)	$(H_3C)_3C-S-$	RSH or other reducing reagents	CF_3COOH, HF, HBr/CH_3COOH
Trityl (Trt)		CF_3COOH, thiols, Hg^{2+}	base, weak acids
4-Methylbenzyl (MeBzl)		HF	CF_3COOH
9-Fluorenylmethyl (Fm)		NH_3/CH_3OH, piperidine	acids

formation of the desired disulfide bonds. An example of this approach is the synthesis of insulin [11].

3.4. Hydroxyl Protecting Groups [1–3]

The side-chain hydroxyl groups of serine, threonine, and tyrosine need not be protected during peptide synthesis because of their poor nucleophilicity. By careful choice of reaction conditions, acylation of the hydroxyl groups (for example, by activated amino acids) can be avoided. However, additional problems may occur with tyrosine because of the aromatic ring system. To avoid possible problems, the hydroxyl groups are best protected, usually as benzyl or *tert*-butyl ethers: the choice depends on the type of amino protection used and the conditions used for final deprotection. The *tert*-butyl group can be removed by acids, such as trifluoroacetic acid, while the benzyl group is liberated by hydrogenolysis, hydrofluoric acid, and sodium in liquid ammonia.

3.5. Imidazole Protecting Groups [1–3]

Protection of the secondary amine in the imidazole ring of histidine is not essential, though often desirable. Even though nitrogen is a relatively weak nucleophile, acylation can occur and the unprotected imidazole ring can catalyze the hydrolysis of ester and amide bonds and also racemization, especially if the histidine is the C-terminal residue. Of the histidine (imidazole) protecting groups listed in Table 4, only the

Table 4. Imidazole protecting groups

Protecting group (abbreviation)	Structure	Cleavage agents	Stability
Benzyl (Bzl)	$-CH_2-$	H_2/Pd, Na/NH_3	acids, base
Trityl (Trt)	$[-C_6H_5]_3C-$	CF_3COOH, H_2/Pd, HBr/CH_3COOH	weak acids
2,4-Dinitrophenyl (Dnp)	$O_2N-C_6H_4-NO_2$	thiols, hydrazine	acids
tert-Butoxycarbonyl (Boc)	$(H_3C)_3C-O-CO-$	HF, HBr/CH_3COOH	base, HCl/dioxane
Adamantyloxycarbonyl (Adc)	$C_{10}H_{15}-O-CO-$	CF_3COOH	HCl/dioxane
4-Toluenesulfonyl (Tos)	$H_3C-C_6H_4-SO_2-$	HF, Na/NH_3	H_2/Pd
π-*tert*-Butoxymethyl (Bum)	$(H_3C)_3COCH_2-$	weak acids	H_2/Pd, base
π-Benzyloxymethyl (Bom)	$-CH_2OCH_2-$	H_2/Pd, HF	weak acids

π-benzyloxymethyl [12], π-*tert*-butoxymethyl [13], and trityl [14] groups seem to effectively suppress racemization.

The type of protecting group used for histidine depends on the planned strategy. Much of the peptide synthesis in solution is carried out without protection of histidine. In solid-phase synthesis, however, this amino acid is almost always protected, for example, by the tosyl (Tos) or 2,4-dinitrophenyl (Dnp) groups.

3.6. Protecting Groups for Guanidine [1–3]

The unusually basic guanidino group of arginine can be "protected" by protonation, for example, as a hydrochloride or hydrobromide salt. This is usually sufficient to prevent side reactions under the conditions used for peptide synthesis in solution. However, arginine salts have poor solubility in organic solvents, which often prompts the use of protected derivatives. For the same reason, protected arginine derivatives, such as the 4-toluenesulfonyl (Tos) or nitro derivatives, are usually used in solid-phase synthesis. Several new protecting groups have been developed, especially for use in combination with the Fmoc group [15–17] (see Table 5). The specific choice of protecting groups for the guanidino function depends on the strategy being used to synthesize the desired peptide.

3.7. Other Protecting Groups

The primary amide groups of *asparagine* and *glutamine* are relatively unreactive and, therefore, in theory, do not need to be protected. However, the use of protecting groups offers the advantage of increased solubility, as well as avoidance of dehydration of the amide function during activation. The most commonly used protecting groups for this purpose are the xanthyl and 4,4′-dimethoxybenzhydryl groups [1–3], both of which are removed under acidic conditions.

Methionine, although rarely thought of as being reactive, can undergo S-alkylation. This can be avoided through use of the sulfoxide, which is converted back to the thioether with 1,4-dimercapto-2,3-butanediol [*27565-41-9*] (Cleland's reagent) [18].

The secondary amine function of the indole group of *tryptophan* is oxidized relatively easily and may also be alkylated at acidic pH. The only useful method of protection is the formyl (For)

Table 5. Guanidino protecting groups

Protecting group (abbreviation)	Structure	Cleavage agents	Stability
Nitro (NO_2)	O_2N-	HF, H_2/Pd	acids, bases
Benzyloxycarbonyl (Z or Z_2)		H_2/Pd	acids, bases
Adamantyloxycarbonyl (Adc)		CF_3COOH	H_2/Pd, base
4-Toluenesulfonyl (Tos)		HF, Na/NH_3	H_2/Pd, CF_3COOH
4-Methoxybenzenesulfonyl (Mbs)		HF	H_2/Pd, CF_3COOH
2,4,6-Trimethylbenzenesulfonyl (Mts)		CF_3COOH	H_2/Pd, bases
2,3,4,5,6-Pentamethylbenzenesulfonyl (Pms)		CF_3COOH	H_2/Pd, bases
4-Methoxy-2,3,6-trimethylbenzenesulfonyl (Mtr)		CF_3COOH	H_2/Pd, bases
2,2,5,7,8-Pentamethylchroman-6-sulfonyl (Pmc)		CF_3COOH	H_2/Pd, bases

group, which is stable under the acidic conditions used during peptide synthesis. Deprotection is accomplished through use of hydrazine in dimethylformamide [19].

4. Formation of the Peptide Bond

The principal reaction in peptide synthesis is the acylation of the amino group of one amino acid by the carboxyl group of a second amino acid, resulting in the formation of a peptide bond. However, because of the diversity of structure of amino acids, peptide bond formation is far more complicated than simple carboxamide formation. For this reason, a variety of methods of peptide bond formation have been developed, based on enhancement of the electrophilicity of the carboxyl carbon atom by using electronegative substituents. Aminolysis of the activated amino acid derivatives then results in peptide bond formation. This reaction may be divided into two steps:

$$\text{Activation:}\quad R-\overset{O}{\overset{\|}{C}}-OH \longrightarrow R-\underset{(\delta+)}{\overset{O}{\overset{\|}{C}}}-X\ (\delta-) \qquad (1)$$

$$\text{Aminolysis:}\quad R-\underset{(\delta+)}{CO}-X\ (\delta-) + H_2\ddot{N}-R' \xrightarrow{-HX} R-CONH-R' \qquad (2)$$

Practically, the reaction may be accomplished in three principal ways:

1) Activation of the carboxyl group followed by aminolysis
2) Isolation and purification of the activated carboxyl component, followed by aminolysis
3) Activation of the carboxyl component through use of a coupling reagent in the presence of the amine component

Some of the most commonly used methods follow.

4.1. Active Ester Method

Active esters of protected amino acids are prepared by the following general scheme:

The greater the degree of activation of the carboxyl group, the faster the subsequent aminolysis. For this reason, virtually all of the useful active esters are of the aryl type; their activities vary widely as a function of the substituents on the aromatic ring. The most commonly used active esters are listed in Table 6. The *N*-succinimidyl ester has been used extensively because of its ability to suppress the racemization that can occur during activation and coupling. The sterically hindered pentachlorophenyl ester has largely been replaced by the pentafluorophenyl ester, especially in conjunction with Fmoc protection. However, both of these esters are expensive and they also liberate pentachloro- and pentafluorophenol as byproducts, which are a potential source of dioxins. 8-Oxo-1,8-dihydrobenzo-1,2,3-triazine esters are not often used on a large scale [20].

Table 6. Active esters

Active ester group (abbreviation)	Structure
4-Nitrophenyl ester (-ONp)	2,4,5-Trichlorophenyl ester (-OTcp)	Pentachlorophenyl ester (-OPcp)	Pentafluorophenyl ester (-OPfp)	N-Succinimidyl ester (-OSu)	8-Oxo-1,8-dihydrobenzo-1,2,3-triazine ester (-ODhbt)	Benzo-1,2,3-triazole ester (-OBt)	
4.2. Anhydride Method

Two types of anhydride are used in peptide synthesis: symmetrical anhydrides and mixed anhydrides.

Symmetrical anhydrides (which are generally formed by reacting the protected amino acid with half an equivalent of carbodiimide) react in the following manner:

Although this procedure works well, it is relatively expensive because only one of the two amino acid molecules in the anhydride is incorporated into the growing peptide chain.

In the *mixed anhydride method*, two possible reactions can occur with the amine component:

Since the second carboxyl component (R^2-COOH) of the mixed anhydride is not usually derived from an amino acid, reaction of the amine component at this carbonyl group does not give the desired peptide product. Furthermore, since reaction occurs preferentially at the more positively charged and less sterically hindered carboxyl group, mixed anhydrides can be designed to promote the formation of the desired peptide, for example:

In this case, the R^1 group (derived from the protected amino acid) is electron-withdrawing, while the R^2 group is a sterically hindered, electron-donating group. If conditions are chosen carefully so that the reaction occurs rapidly, little or no racemization occurs.

4.3. Azide Method

The azide method has proved to be one of the most important developments in the peptide field and may be considered the starting point for modern peptide synthesis. Even today, it is still one of the most important coupling methods, because it has significant advantages:

1) Low potential for racemization
2) Ease of crystallization, allowing purification of intermediates
3) Useful in syntheses with minimum side chain protection
4) Useful for the assembly of large peptide fragments

The azide procedure is carried out in three steps:

Despite possible side reactions, the azide method has been used widely in peptide fragment condensations, the optimal size range being peptides of up to about 50 amino acids. Special applications of this method include peptide cyclizations and the synthesis of polyamino acids.

4.4. Carbodiimide Method

The carbodiimide method, based on the use of dicyclohexylcarbodiimide (DCC) [*538-75-0*], effectively results in the elimination of water to form the peptide bond:

DCC is a highly reactive reagent, which reacts faster with the carboxyl groups than with the amine components. The *N,N′*-dicyclohexylurea formed during the reaction has low solubility in solvents used for coupling reactions and is therefore easily removed as a precipitate. Unfortunately, the method is accompanied by a number of side reactions, including:

1) Racemization
2) Partial dehydration of the carboxamide groups of asparagine and glutamine to nitrile groups
3) Formation of *N*-acylureas

Investigations of methods to suppress these side reactions have led to the use of α-dinucleophiles, such as *N*-hydroxysuccinimide (**5**) [*6066-82-6*], 1-hydroxybenzotriazole (**6**) [*2592-95-2*], and 1-hydroxy-8-oxo-1,8-dihydrobenzo-1,2,3-triazine (**7**) [*28230-32-2*]:

5 **6** **7**

The combination of dicyclohexylcarbodiimide and 1-hydroxybenzotriazole is still the most widely preferred coupling method, both in solid-phase and solution synthesis.

5. Strategies for Peptide Synthesis

Due to the wide variety of protecting groups and synthetic methods, the synthetic route for a particular peptide must be chosen carefully. The actual method used (solid-phase synthesis, synthesis in solution, stepwise or fragment condensation, or other methods) depends on a number of factors, including the length and sequence of the peptide and the scale of the synthesis.

5.1. Synthesis in Solution

Many of the peptides that are required in large quantities (e.g., glucagon, γ-endorphin) are still synthesized by solution methods. Once the synthetic route has been elaborated, production can be carefully controlled because intermediates are isolated and characterized at each step. Generally, scaleup of this type of synthesis is relatively straightforward. In principle, the method can be applied in two ways:

1) Repeated, stepwise addition of single amino acid residues to the growing peptide chain
2) Synthesis of segments of the peptide which are subsequently assembled to give the desired sequence (fragment condensation).

Stepwise Synthesis. Protecting groups of the urethane type effectively suppress racemization of amino acids during activation and coupling (Section 3.5), forming the basis of a highly efficient method for synthesizing peptides. The applicability of the method was first demonstrated successfully in the synthesis of oxytocin (9 amino acids) [21], in which *N*-α-Z-protected amino acid 4-nitrophenyl esters were used. Protected intermediates were purified by washing and crystallization. The process was relatively efficient – a new amino acid residue could be introduced every two days. The same process has been applied successfully to the synthesis of even larger peptides, such as secretin (27 amino acids) [22] and gastrin (17 amino acids) [23]. However, this approach does present some problems, especially as the peptide chain becomes longer. First, the effective molar concentration of the amine component decreases with the increase in molecular mass of the growing peptide chain thus necessitating longer coupling times. Secondly, as the size of the protected peptide increases, the solubility often decreases dramatically in the solvents commonly used for peptide synthesis (e.g., dichloromethane, dioxane, tetrahydrofuran, dimethylformamide).

Fragment Condensation. Because of some of the problems discussed above, an alternative strategy has been developed in which a series of fragments of the desired sequence (up to 10 or sometimes 15 amino acid residues) are synthesized in parallel. Even though this minimizes some of the problems, especially those relating to the insolubility of large, protected peptides, final assembly of the fragments still requires considerable preparative skill. The method is often limited by low yields in the fragment coupling steps (often due to insolubility), although use of amino acid derivatives with solubilizing protecting groups may be helpful. Unfortunately, it is virtually impossible to predict the efficiency of a synthesis because of the lack of knowledge concerning the relationship between sequence and physicochemical properties of protected peptides. Even so, the fragment condensation approach is useful for the synthesis of peptides of all sizes; optimization can lead to economical production methods in which reliable quality control of intermediates can be carried out.

5.2. Solid-Phase Synthesis

Synthesis of peptides in solution can be extremely time consuming due to the necessity of purifying and characterizing the intermediates, as well as the final product. In 1963, MERRIFIELD introduced a very powerful, alternative strategy, in which the growing peptide chain was attached to a swollen, insoluble polymeric support throughout the synthesis [24]. The matrix acts as a tool for purification; simple filtration and washing steps can be used to remove excess reagents and byproducts before continuing to the next step. Furthermore, reactions can be carried out under optimal, "forcing" conditions through use of relatively large molar excesses of reagents, resulting in reduced reaction times. Because the technique is simple and rapid and easily automated, it has found widespread application.

At the present time, the most commonly used polymeric supports are the polystyrene-based resins, originally introduced by MERRIFIELD, and the more recently developed polyamide supports. The C-terminal amino acid in the sequence is attached to the polymeric support via a benzyl ester linkage (or, in the case of a C-terminally amidated sequence, via a labile amide linkage) and amino acids are added repetitively to build up the desired sequence. In the original Merrifield approach, based on N-α-Boc and benzyl–based side-chain protection, the following cycle is used:

1) Cleavage of the Boc group with 50 % trifluoroacetic acid in dichloromethane
2) Neutralization with 10 % triethylamine in dichloromethane
3) Coupling of Boc-amino acids using dicyclohexylcarbodiimide in dichloromethane.

The assembled peptide is cleaved from the resin with anhydrous, liquid hydrogen fluoride, simultaneous cleavage of the side-chain protecting groups gives the crude product. However, hydrogen fluoride can lead to side reactions and many improvements have therefore been made to the original method, such as the development of new protecting groups and resins and methods for monitoring coupling steps and suppressing side reactions during the hydrogen fluoride treatment step [1], [4]. Alternative protecting group combinations which do not require the use of hydrogen fluoride (e.g., that based on the Fmoc group) are also receiving increased attention. Even though the solid-phase technique is rapid and convenient, it is not completely routine and has inherent limitations. Since there are no intermediate purification steps, each coupling step must be as complete as possible. Incomplete reaction or side reactions can lead to the formation of side products (e.g., "failure sequences" or "truncated peptides") which must be removed during the final purification step. Purification of the final product can therefore present a considerable challenge, although the introduction of preparative, reverse-phase high performance liquid chromatography (HPLC) has made the solid-phase technique extremely powerful. A number of products (e.g., calcitonin, somatostatin) are now manufactured on a large scale for use as pharmaceuticals using this technique.

5.3. Other Synthetic Methods

5.3.1. Liquid-Phase Synthesis

The liquid-phase method combines the advantages of solid-phase synthesis and synthesis in solution [25]. As with the solid-phase method, the C-terminal amino acid in the sequence is covalently attached to a polymer, in this case a soluble poly(ethylene glycol). Synthesis is carried out by stepwise addition of amino acid derivatives in homogeneous solution because of the soluble nature of the polymeric support. Because the physical properties of the peptide are dominated by the polymer, few of the solubility problems associated with solution syntheses are experienced in this method. Furthermore, intermediate purification can be effected by precipitation of polymer-bound peptides and washing to remove excess reagents. Aggregation problems are sometimes encountered when the growing peptide chain forms secondary structures. Although the method has attractive advantages, it has not gained widespread acceptance.

5.3.2. Semisynthesis

Selective modification of natural sequences can provide an approach for obtaining new

molecules. Although this method has largely remained a research tool, a notable example of its use on a commercial scale to manufacture a pharmaceutical product is the conversion of porcine to human insulin [26]. This transformation involves replacement of the C-terminal alanine residue of the B-chain of the porcine sequence with a threonine residue. This is accomplished in a two-step process by cleaving the alanine residue and subsequently attaching the threonine [27]; or directly, in a single-step transpeptidation reaction, catalyzed, for example, by trypsin [26]. The semisynthesis approach is likely to find its widest application in combination with the recombinant method (see Section 5.3.4) for the production of analogues of peptides or proteins which cannot be produced directly via the recombinant approach.

5.3.3. Enzymatic Synthesis

Although the use of proteases (e.g., papain and pepsin) as catalysts for the formation of peptide bonds was reported in 1937 [28], the method has only been studied extensively since the early 1980s. This method offers a number of advantages over chemical methods [29] including the use of unprotected or partially protected amino acids, without the need for side-chain protecting groups as well as racemization-free coupling because of the stereoselectivity of the enzymes used. However, in practice, a number of problems make this method less successful than it initially promised to be. Each coupling reaction in the enzymatic method is unique and must therefore be optimized. The method is not universal and certain couplings, such as that between cysteine and proline, cannot be carried out [30]. D-Amino acids are also difficult or impossible to couple. However, the fact that enzymatic synthesis is normally carried out under aqueous conditions or in a mixture of aqueous and organic solvents, may lead to important applications in which chemical and enzymatic methods are combined.

5.3.4. Recombinant DNA-Based Synthesis

One of the newest methods for peptide production, which has only been available since the early 1970s, is the "recombinant DNA approach". This method has been the subject of extremely intensive investigation because it offers tremendous potential for the production of both peptides and proteins. Genetically engineered microorganisms are used to produce large quantities of peptides and proteins through their normal metabolic processes (→ Genetic Engineering).

The sequence for a particular peptide is encoded in a gene which can either be obtained from a DNA library or synthesized rapidly in small quantities. This gene is then inserted into a host plasmid DNA by using highly specific enzymes. A suitable microorganism, such as yeast or *Escherichia coli*, must be found in which the gene is expressed, i.e., used as a template to synthesize the desired peptide or protein. The product must then be extracted and purified.

The majority of syntheses which have been carried out on a production scale appear to have concentrated on molecules which are not readily accessible by other routes, in particular proteins such as human growth hormone [31], interferons [32], and human insulin [33]. Although problems still exist, especially for the production of small peptides (poor expression, toxicity, bacterial inclusions, proteolytic degradation), these will probably be solved in the near future and this approach may therefore be the method of choice. Chemical synthesis is, however, still likely to remain the most practical approach for very small peptides and peptides containing unnatural sequence modifications.

5.3.5. Concluding Remarks

A tremendous number of peptides have been discovered (→ Peptide and Protein Hormones). These peptides, isolated from the pancreas, gut, lungs, and even the heart, were recognized as new regulators with great potential for pharmaceutical use. Thus, the need for synthetic peptides has become even greater than ever. Of the methods which are available for the production of peptides, there is no doubt that the recombinant approach will eventually play the most important role. Meanwhile, enzymatic synthesis has not achieved any significance as a production method. Semisynthesis is employed for the production of insulin (Nova and Hoechst). Chemi-

Table 7. Examples of peptides of pharmaceutical significance

Peptide	No. of amino acids	Use	Trade name (company)
Atrial natriuretic factor	28	hypertension	
Arginine-vasopressin	9	antidiuretic	
Calcitonin (salmon)	32	treatment of osteoporosis	Karil (Sandoz) Calsynar (Rorer)
Calcitonin (eel)	32	treatment of osteoporosis	
Corticotropin	39	treatment of inflammation	Acethropan (Hoechst)
Corticotropin releasing factor	41	diagnosis of Cushing's syndrome	
Insulin	51	treatment of diabetes	(Hoechst, Nordisk, Lilly, Novo)
Human parathyroid hormone	34	diagnosis of calcium metabolism disorders	
Glucagon	29	treatment of hypoglycemia	(Lilly, Novo)
Growth hormone releasing factor	29, 44	diagnosis and treatment of growth disorders	Somatobiss (Bissendorf Peptide)
Luteinizing hormone releasing factor	10	diagnosis of hypophyseal function	Retefac (Hoechst), GnRH-Serono (Serono)
Oxytocin	9	induction of labor in pregnancy	Orasthin (Hoechst), Syntocinin (Sandoz)
Somatostatin	14	control of gastric bleeding	Aminopan (Union Carbide), Stilamin (Serono)

cal synthesis plays the most important role. On a small scale (milligrams to grams) the solid-phase method is the most powerful and the most routine. However, as the scale of the synthesis increases (hundreds of grams to kilograms) solution synthesis will probably play an increasingly important role. At the present time solution synthesis is mostly used but solid-phase synthesis is becoming increasingly important.

6. Cleavage of Protecting Groups

Due to the wide variety of protecting groups, a correspondingly large variety of deblocking procedures are available.

Acidolysis. Deprotection by acidolysis is widely used because a large number of protecting groups are removed simultaneously by acids. The most commonly used acidic reagents are trifluoroacetic acid, liquid anhydrous hydrogen fluoride, and hydrochloric or hydrobromic acids in glacial acetic acid or organic solvents. The peptide can, for example, be dissolved in trifluoroacetic acid and left to stand for 1 h. The deblocked peptide is then precipitated with diethyl ether. Anhydrous hydrogen fluoride cleaves most of the protecting groups and is therefore often used during the final deprotection step, despite its inherent toxicity and corrosive properties. This reagent can, however, often be replaced by trifluoromethanesulfonic and fluorosulfonic acids.

Catalytic hydrogenolysis is also a popular method for deprotection, because of its mildness. It is used to remove benzyloxycarbonyl groups, nitro groups (used to protect the side chain of arginine), benzyl ester groups, and benzyl ether groups. The protected peptide is dissolved in methanol and treated with hydrogen in the presence of a catalyst (10 % palladium on charcoal). This method is ineffective when sulfur- containing residues are present.

Deprotection under alkaline conditions (e.g., saponification of peptide ethyl ester with 1 mol/L NaOH for 2 h) is relatively important, although it may be accompanied by several side reactions, including racemization. Deprotection may be carried out using hydroxyl ions, hydrazine, thiolysis, or rhodanolysis. Treatment of the peptide with sodium in liquid ammonia is also an effective method of deprotection, but is not widely used. *Other procedures* are described in [1–8].

7. Purification of Peptides

Purification of peptides by crystallization is difficult or often impossible because peptides rarely crystallize or, if they do, they usually cocrystallize with impurities. Other (chromatographic)

techniques must therefore be used, see also → Process-Scale Chromatography.

Gel chromatography is a simple, powerful technique because it can be applied both in aqueous and in organic solvents. Thus, both water-soluble and water-insoluble (protected) peptides can be purified. This technique separates components mainly on the basis of their molecular mass. The most common gels– cross-linked dextrans (Sephadex) and cross-linked polyacrylamides–are available in a number of different pore sizes, making them suitable for the purification of peptides and proteins with a wide range of molecular masses.

Liquid partition chromatography relies upon the distribution of materials between two (usually immiscible) liquid phases, one of which is a moving phase, while the other is dispersed on a carrier phase, such as Sephadex, cellulose, or aluminum oxide. The technique is often faster and more efficient than liquid – liquid extraction.

Liquid – liquid extraction is based on the fact that the main product and the side products have different distribution coefficients in two immiscible solvents (e.g., butanol and acetic acid) [34]. The technique can be automated and used to purify kilogram quantities of peptides. Examples of liquid phases are butanol – acetic acid – water (volume ratios 4 : 1 : 5) and butanol – pyridine – acetic acid–water (volume ratios 4 : 2 : 1 : 7).

Ion-exchange chromatography is widely used because of its efficiency and relatively easy scaleup. Chromatography is carried out on supports which bear negatively or positively charged functional groups on which the peptide is adsorbed and subsequently desorbed by varying the pH or salt concentration. Since the charge on molecules is sensitive to structure and microenvironment, this technique separates peptides and proteins on the basis of both charge and structure.

Reverse-phase high performance liquid chromatography (HPLC) is the most powerful method for the purification of peptides. It relies mainly on hydrophobic interactions between the products and a matrix (usually silica derivatized with a long carbon chain). Through careful choice of conditions, peptides can be purified extremely rapidly, and large-scale equipment is now available which allows purification on a kilogram scale.

8. Analytical Control of Peptides

Because of the complexity of peptides, no single analytical method can be used to assess the purity of a peptide after purification. Although traditional methods (e.g., thin layer chromatography and paper electrophoresis) have been used, analytical, reverse-phase HPLC is now largely employed. Larger peptides and proteins can also be analyzed by gel electrophoresis. It is also important to confirm the amino acid composition of the peptide, as well as the optical purity of the constituent amino acids by amino acid analysis [35]. The peptide is hydrolyzed with strong acid (usually 6 mol/L hydrochloric acid), and the resulting mixture of amino acids is quantitatively separated by ion-exchange chromatography. Analysis for racemization is carried out by using gas chromatography to separate enantiomers [36]. The correctness of the amino acid sequence may be confirmed by Edman degradation [37]. Mass and NMR spectroscopy provide additional confirmation of the structure and also confirm the absence of residual protecting groups from the synthesis.

9. Important Commercial Peptides

The list of peptides which are reaching the market place as both diagnostic and therapeutic products is increasingly constantly. Some peptides with important pharmaceutical applications are listed in Table 7.

1. Introduction

Although perfumes are alcoholic – aqueous solutions of perfume oils, the term "perfume" is often used to denote concentrated perfume oil. Perfume oils may be composed of complex natural products, as well as natural or synthetic fragrance substances. The art of perfumery consists of combining a wide range of raw materials to create a harmonious, pleasant, and expressive fragrance.

History. Mixtures of fragrance substances (odorants) in the form of incense (Latin *perfumum*) and perfumed unguents were used for ceremonial purposes in early times. Along with their ritual uses, perfumes became important among the Greeks and Romans as luxury items. After the isolation of essential oils from green plants, bark, wood, and herbs the art of perfumery advanced rapidly and became fully established during the Renaissance. French perfumery has held a dominant position in Europe since the reign of Louis XII (ca. 1500).

Around 1700, Giovanni Paolo Feminis, an Italian who had migrated to Cologne, began marketing what later became eau de cologne. The classic formula for this product consists of bergamot oil, lemon oil, orange oil, and orange flower oil in ethanol. The original name *aqua mirabilis* (marvellous water) was replaced by *aqua coloniensis* and *Kölnisch Wasser* (Colonia is the Latin name of the city of Cologne, and Köln is its German name), and finally, by eau de cologne. Several firms in the city, including Johann Maria Farina and 4711, made eau de cologne a world-famous product.

Modern perfumery began at the end of the 19th century when the first synthetic fragrance substances became available. The initially modest selection of natural products was subsequently extended in a few decades as a result of intensive research and advances in production technology. The importance of perfumery has increased greatly since then. It includes not only the manufacture of fine products (perfume and eau de cologne), but also the use of perfumes in cosmetics, toiletries, soaps, and household or industrial products.

In addition to French perfumery, North American perfumery has become very important in recent years. With respect to distinctive fragrance types as well as market volume, these two sources now enjoy a virtually equal status.

2. Raw Materials and Production

The raw materials used in perfumery are essential oils, floral oils, extracts from plants and from animal secretions, fragrance substances isolated from natural products, and purely synthetic aroma chemicals. The number of natural fragrance substances is limited, but the increasing refinement of analytical techniques continues to yield new and interesting natural products. Chemical synthesis is, however, mainly responsible for the steady stream of innovations in perfumery since the turn of the 20th century.

The production and properties of aroma chemicals and fragrance substances are described elsewhere (→ Flavors and Fragrances).

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a19_171

Raw Materials of Plant Origin. The following products are isolated from plant raw materials:

1) *Essential oils*, obtained by pressing plant materials or by steam distillation
2) *Concretes*, obtained by extraction with volatile solvents such as petroleum ether, benzene derivatives, or alcohols
3) *Resinoids*, produced by extraction of aromatic resins, mosses, balsams, and roots with volatile solvents
4) *Absolutes*, derived by treating concretes and resinoids with ethanol

The starting materials for these products are

1) *flowers* such as lavender, rose, jasmine, and neroli (orange flower);
2) *stalks and leaves* such as geranium, patchouli, and petitgrain;
3) *fruit* such as anise, coriander, caraway, cumin, and juniper;
4) *peel of citrus fruits* such as bergamot, lemon, and orange;
5) *seeds* such as mace, angelica, celery, and cardamom;
6) *roots* such as angelica, costus, and iris;
7) *wood* such as sandalwood, guaiac, cedar, and bois de rose;
8) *herbs and grasses* such as tarragon (estragon), lemongrass, sage, and thyme;
9) *needles and twigs* of spruce, fir, and pine; and
10) *resins and balsams* such as those derived from galbanum, elemi, benzoin, myrrh, olibanum, and opopanax.

Both the natural products and the aroma chemicals isolated from them are employed in perfumery. Examples of the latter are geraniol and citronellal from citronella oil, citral from lemongrass or *Litsea cubeba* oil, eugenol from clove oil, and menthol from peppermint oil.

Raw Materials of Animal Origin. Raw materials of animal origin are becoming increasingly rare and expensive. The following are used:

1) *Ambergris*, a metabolic product excreted by sperm whales that may result from a pathological condition
2) *Musk*, a glandular secretion of a hornless deer of Central Asia
3) *Civet*, a glandular secretion of the civet cat
4) *Castoreum*, a glandular secretion of the beaver

Semisynthetic and Synthetic Aroma Chemicals. *Semisynthetic products* are obtained by chemical modification of a natural starting material. They include hydroxycitronellal from citronellal, citronellol from geraniol or citronellal, geranyl acetate from geraniol, and ionones and methylionones from citral.

Purely *synthetic fragrance substances* are produced from basic chemicals by complete synthesis. They can be divided into products that are identical to natural ones and products that do not occur in nature. Products identical to natural substances but obtained by chemical synthesis include benzyl acetate from toluene, phenethyl alcohol from benzene, menthol from thymol, and linalool, a product of acetylene synthesis.

Other synthetic aroma chemicals have molecular structures completely different from those of natural products. They can be produced only by chemical synthesis, and often imitate the olfactory impressions of natural raw materials. Examples are 4-*tert*-butylcyclohexyl acetate (woody note, violet note), α-amylcinnamaldehyde (jasmine), 4-*tert*-butyl-α-methylhydrocinnamaldehyde (cyclamen), musk ketone (musk), and ethylene brassylate (musk).

Many natural products will continue to be indispensable in perfumery. However, synthetic products are playing an increasingly important role in the perfumer's assortment of raw materials because of their virtually unrestricted availability, constant quality, and generally steady price. Modern analytical techniques allow identification of the components of natural mixtures, which are often very complex. Reconstitution of these products and of essential oils by synthetic materials has led to substitutes with olfactory distinction.

Fixatives. Fixatives are used to equalize the vapor pressures, and thus the volatilities, of the raw materials in a perfume oil, as well as to increase the tenacity.

Natural fixatives are resinoids (benzoin, labdanum, myrrh, olibanum, storax, and tolu

Table 1. Floral bouquet

Composition		Quantity, g	Compound
Top note		5	2-undecylene aldehyde
		5	ω-decenol
		20	2,6-dimethyl-2-heptanol
		60	dihydromyrcenol
		50	bergamot oil
		30	linalool
		10	neroli oil
Floral complex	rose	50	citronellol
	rose	30	geraniol
	rose	80	phenethyl alcohol
	lilac	25	terpineol
	jasmine	75	α-hexylcinnamaldehyde
	jasmine	25	α-amylcinnamaldehyde
	jasmine	30	benzyl acetate
	lily of the valley	120	4-*tert*-butyl-α-methylhydrocinnamaldehyde
	lily of the valley	40	4-(4′-hydroxy-4′-methylpentyl)-3-cyclohexene carboxaldehyde
	lily of the valley	10	4-isopropyl-α-methylhydrocinnamaldehyde
	gardenia	15	styrolyl acetate
	iris – violet	60	γ-methylionone
	iris – violet	25	4-*tert*-butylcyclohexyl acetate
	clove	10	eugenol
	clove	5	eugenol methyl ether
Fixation	sweet	25	cinnamic alcohol
	sweet	20	coumarin
	wood	60	acetylcedrene – acetylthujopsene
	ambergris	5	1,2-furano-2,5,5,8a-tetramethyldecalin (10 %) in diethyl phthalate
	musk	70	6-acetyl-1,1,2,4,4,7-hexamethyltetralin
	musk	10	cyclopentadecanolide
	musk	30	musk ketone (4-*tert*-butyl-2,6-dimethyl-3,5-dinitroacetophenone)
		1000	

balsam) and animal products (ambergris, castoreum, musk, and civet). Synthetic fixatives include substances of low volatility (cyclopentadecanolide, ambroxide, benzyl salicylate) and virtually odorless solvents with very low vapor pressures (benzyl benzoate, diethyl phthalate, triethyl citrate).

Solvents. The only solvent used in fine perfumery is extremely pure ethanol that is diluted with water to the required concentration. Weakly odorous synthetic fixatives are used as solvents for alcohol-free perfumes, especially bazaar oils. (Bazaar oils are perfume oils that are dissolved in an oily solvent; they are sold in bazaars in Arabian countries and used as perfumes.)

Production. Perfumes were originally prepared from alcoholic infusions, solutions, and tinctures of floral extracts, essential oils, natural and artificial aroma chemicals, drugs, and resins. The long storage times allowed complete clarification and maturing of the alcoholic solutions, so that the perfumes required a much shorter aging time. As a result of increasing industrialization, perfumery has departed from these classical methods of preparation. Today, perfume compositions prepared in the form of perfume oils are dissolved in ethanol, cooled to ca. 0 °C, filtered, packaged, stored, and marketed. Perfume (extrait) may be for example, a 10 – 20 vol% solution of a perfume oil in ca. 90 – 95 vol% ethanol. An eau de toilette or eau de parfum contains ca. 7 – 10 vol % perfume oil in 80 – 90 vol % ethanol; an eau de cologne (Kölnisch Wasser), up to 4 vol % perfume oil in ca. 70 – 85 vol % ethanol.

3. Perfume Compositions

In building up a composition, the perfumer must work systematically and observe certain rules of workmanship. A fragrance can be divided into three parts:

1) Top note or initial fragrance impression
2) Body note or middle note
3) End note or dry out

The odor must pass smoothly from one phase of this "cycle" to the next; the overall character of the perfume should be clearly perceptible from the top note to the end note, and must impart its own unmistakable note to the fragrance.

Linear Compounding. A sample formula is described to illustrate the formulation of a floral fragrance. This formula also demonstrates the technique of "linear" composition, which is based primarily on well-defined aroma chemicals, essential oils, and floral oils. "Complex" compounding, on the other hand, mainly uses predesigned and balanced perfume bases and fragrance complexes.

Sample Formula. The fragrance materials in the "floral bouquet" (Table 1) correspond to a variety of flowers; they give a basic, inherently rounded floral complex. Nuancing agents for the top note are fresh-flower components such as ω-decenol and 2,6-dimethyl-2-heptanol, whereas several sweet, woody, and musk odorants such as acetylcedrene – acetylthujopsene and 6-acetyl-1,1,2,4,4,7-hexamethyltetralin serve as fixatives.

Table 2. Rose base

Composition	Quantity, g	Compound
Top note	15	2-undecylene aldehyde (10 %) in diethyl phthalate
	5	ω-decenol
	5	phenylacetaldehyde dimethyl acetal
	20	decanal (1 %) in diethyl phthalate
Body	300	phenethyl alcohol
	200	citronellol
	100	geraniol
	20	geranyl acetate
	160	phenethyl diethylacetate
	25	nerol
	20	farnesol
	25	nerolidol
	5	eugenol
Fixation	20	trichloromethylphenyl carbinyl acetate
	30	cinnamic alcohol
	50	phenethyl phenylacetate
	1000	

Complex Compounding. In complex compounding, separately balanced perfume bases are used instead of individual fragrance materials or fragrance accords. These bases consist of numerous components; appropriate mixtures of synthetic products are also substituted for the fragrance complexes of natural essential oils.

The complex method yields a more well-rounded composition than a number of individual fragrance materials. For example, the simple rose accord in the "floral bouquet" (Table 1), consisting of citronellol, geraniol, and phenethyl alcohol, can be replaced by a rose base (Table 2) whose composition has been worked out in much more detail.

Replacement of fragrance notes composed of a few substances, as described in Table 1, by sophisticated perfume bases of appropriate odor type yields a composition consisting of several hundred components that has an exceedingly complex makeup and a very rounded odor.

4. Development of Extrait Perfumes

4.1. Fragrance Concepts

Extrait perfumes set the trends for all developments in perfumery. They are important for any creative perfumer, regardless of the application for which new fragrance compositions are being developed. The many perfumes now on the market can be classified according to three main fragrance concepts:

1) **Floral concept**
   a) Characteristic raw materials:

Benzyl acetate (jasmine)
α-Amylcinnamaldehyde (jasmine)
α-Hexylcinnamaldehyde (jasmine)
Indole (jasmine)
Jasmine absolute (jasmine)

Terpineol (lilac)
Anisaldehyde (lilac)

Phenethyl alcohol (rose)
Geraniol (rose)
Citronellol (rose)
Rose oil (rose)

Hydroxycitronellal (lily of the valley)
4-*tert*-Butyl-α-methylhydrocinnamaldehyde (lily of the valley)
4-(4-Hydroxy-4-methyl-pentyl)-3-cyclohexene carboxaldehyde (lily of the valley)

Ionones (iris – violet)
Methylionones (iris – violet)

Eugenol (clove)
Isoeugenol (clove)
Clove oil (clove)

b) Typical products:
Joy (Patou, 1935); L'Air du Temps (Ricci, 1948); Fidji (Laroche, 1966); Diorella (Dior, 1972); Charlie (Revlon, 1973); Chloé (Lagerfeld, 1975); Giorgio (Beverly Hills, 1981); Poison (Dior, 1985).

2) **Oriental Note Concept**
a) Characteristic raw materials:
Vanillin, coumarin, tonka bean extract, and musk aroma chemicals
b) Typical products:
Shalimar (Guerlain, 1925); Youth Dew (Lauder, 1952); Opium (St. Laurent, 1977); Must de Cartier (Cartier, 1981).

3) **Chypre Concept**
a) Characteristic raw materials:
Combination of bergamot oil, oakmoss extracts, and patchouli oil
b) Typical products:
Chypre (Coty, 1917); Cabochard (Grès, 1958); Miss Dior (Dior, 1947); Intimate (Revlon, 1955); Coriandre (Couturier, 1973); Ysatis (Givenchy, 1984).

4.2. Fragrance Notes

Within each fragrance concept, individual fragrance notes can dominate. Examples follow.

1) **Green Note**
a) Characteristic raw materials:
Hexanol, hexenol, and their esters; galbanum oil
b) Typical products:

Chypre concept: Ma Griffe (Carven, 1944)

5. Perfumes for Cosmetics, Toiletries, and Household Products

Perfumes and eaux de cologne are used specifically for their odor. In cosmetics, toiletries, and household products, the perfume is usually of secondary importance for the effectiveness of the product; it may, however, strongly influence the consumer's decision to buy a product and, in many cases, represents the only way of making the product's action "perceptible" to the consumer.

Although the model fragrance types are often created in the field of fine perfumery, chemical and physical aspects must also be taken into account in the development of perfume oils for toiletries and household products. For example, the perfume oil used in creams and white soaps must not cause discoloration; a perfume oil for aftershave lotion must be soluble in 50 – 60 % alcohol; the fragrance used in a powdered detergent must be alkali resistant; a fabric softener is expected to leave clothes with a pleasant odor; and even a household cleanser must have a pleasant and functional odor, although active chlorine places extraordinary demands on the stability of the perfume oil. Minimal perfume doses are expected to adequately mask the often strong and unpleasant odors of products such as insecticides, floor cleanser, paints, and varnishes.

Fragrances for soaps must satisfy the following requirements: chemical resistance, low volatility of raw materials (e.g., geraniol and ionone), strength of odor in soap (e.g., citronellal and γ-decalactone), and adhesion to the skin (e.g., 1,2-furano-2,5,5,8a-tetramethyldecalin and α-amylcinnamaldehyde). In

the past, well-defined perfume types such as lavender, citronella, rose, lilac, pine, and fern (fougère) were preferred. Today, however, perfumes are custom formulated, usually in fantasy notes with a fresh, invigorating impact or oriented to fine personal- care cosmetics.

Olfactory enhancement of all types of household products has become increasingly important in recent decades. The development of perfume oils for this wide-ranging field requires a special knowledge of perfumery, as well as information about the chemical and thermal stability of the perfumery materials used and their impact and substantivity in relation to the product being perfumed. [Substantivity denotes the affinity of a perfume material for a substrate, e.g., fibers (fabric conditioners) or hair (hair conditioners).]

6. Economic Aspects

Although no sales figures have been disclosed, worldwide consumption of perfume oils for all applications in 1984 was estimated at ca. 1.8×10^9 €(ca. 2.3×10^9 \$).

Detergents and household products account for ca. 30 % of this total, soaps for 20 %, cosmetics and toiletries for 30 %, and perfumes or eaux de cologne for 20 %.

1. Introduction

Peroxo compounds include hydrogen peroxide (→ Hydrogen Peroxide) and substances derived from hydrogen peroxide by substitution of one or both hydrogen atoms by a metal or a nonmetal such as sulfur, boron, nitrogen, or phosphorous. Peroxides in a wider sense also include the hyperoxides (MO_2), H_2O_2 addition compounds (e.g., sodium carbonate peroxohydrate), and the inorganic ozonides (M^IO_3). In the IUPAC nomenclature, the prefix peroxo is used for inorganic compounds, and peroxy for organic compounds.

A very large number of peroxo compounds have been described in the literature [1 – 5]. This article gives an overview on the properties and industrial applications of the most important peroxo compounds and products of commercial importance.

© 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Due to the low strength of the $-O-O-$ bonding (209 kJ/mol), all peroxo compounds exhibit powerful oxidizing properties. Inorganic peroxo compounds are therefore employed as oxidizing and bleaching agents in the detergents, textile, electronics, and chemical industries.

1.1. History

The first peroxo compounds discovered in the early 1800s by Gay-Lussac and Thenard were the peroxides of barium, sodium, and potassium. Hydrogen peroxide was isolated several years later in 1818 by Thenard. Due to the advantages in stability and handling, the solid peroxides were of greater practical use than hydrogen peroxide solutions. Sodium peroxide gained industrial importance mainly as a bleaching agent in the textile industry and was first produced on a commercial scale by the Castner process in 1899. Sodium peroxide lost its importance when hydrogen peroxide could be more cost-effectively manufactured by the anthraquinone process.

Today the most important industrial peroxo compound is sodium carbonate peroxohydrate. Although discovered in 1899 by Tanatar it only gained commercial importance in the 1990s due to the ecologically driven shift from sodium perborate to sodium carbonate peroxohydrate, especially in Europe. It has nowadays become the preferred bleaching agent in powder laundry and automatic dishwashing detergents since products with good shelf-life properties have become available through new economically viable coating technologies. Sodium peroxoborates, also discovered by Tanatar, in 1898, have been produced on a commercial scale since 1907 and still remain the preferred bleaching agents in powder laundry and automatic dishwashing detergents for climatically challenging regions such as the Middle East, northern Africa, and South and Middle America.

Other industrially important inorganic peroxo compounds are the sodium, potassium, and ammonium salts of peroxodisulfuric acid ($H_2S_2O_8$), the triple salt of potassium peroxomonosulfate ($2\ KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$), and calcium peroxide (CaO_2).

Of the other hydrogen peroxide addition compounds, only urea peroxide is produced on an industrial scale of several hundred tonnes; it has limited applications in pharmaceutical products.

1.2. Classification of Peroxo Compounds

Wannagat [6] proposed that the peroxo compounds should be classified according to their chemical bonding, i.e., whether the bond between the peroxo group and the substituent(s) is heteropolar, covalent, or dative. However, a precise distinction is often impossible, either because of continuous gradation between the bonding types or because the structure has not yet been fully elucidated.

Peroxo Compounds with Heteropolar Bonds. Compounds of this type crystallize in an ionic lattice and contain the colorless, diamagnetic O_2^{2-} anion. The distance between the oxygen atoms is 149 pm. Typical examples of this class are the alkali and alkaline earth metal peroxides $M^{I}_2O_2$ or $M^{II}O_2$.

Peroxo Compounds with Covalent Bonds. The typical example for this group is hydrogen peroxide itself. Whereas the paramagnetic oxygen molecule has a multiple bond (bond length 121 pm), the O–O distance for these compounds is 147 pm, indicating a covalent single bond. The two hydrogen atoms are linked to the O_2 moiety to form a nonplanar structure. Elements of Groups 13–16 of the periodic table, such as boron, carbon, silicon, phosphorus, and sulfur, also form covalent or mainly covalent bonds with the peroxo group. Either one or both hydrogen atoms of hydrogen peroxide can be substituted. Industrially important examples of these compounds are peroxoborates, most organic peroxy compounds (→ Peroxy Compounds, Organic), the silyl peroxides, and the peroxomono- and peroxodiphosphates and -sulfates. Peroxo compounds with covalent bonds to the O_2 group are colorless.

Peroxo Compounds with Dative Bonds. These are metal complexes with peroxo ligands and are formed by polyvalent transition metal cations such as Ti, Cr, Mo, W, and U. They are sometimes colored. An unambiguous assignment is, however, difficult in the case of these

compounds. They can sometimes be regarded as peroxohydrates (see below) or as peroxoacids with covalent bonds. They have no industrial importance.

Peroxohydrates. With many substances hydrogen peroxide forms crystalline adducts in which it behaves like water of crystallization, which may also be present in the crystal structure. The peroxohydrates are also regarded as peroxo compounds.

Hyperoxides are classified as peroxo compounds only in a broad sense. The paramagnetic O_2^- anion (O–O distance: 128 pm, measured in KO_2) is a derivative of the very unstable HO_2 radical. The only known pure hyperoxides are those of the alkali metals, with the exception of lithium.

Inorganic ozonides of the type M^IO_3 are also only classified as peroxo compounds in a broad sense. The name ozonides was proposed by Remy [7]. The O_3^- ion is paramagnetic, as is the O_2^- ion, and has a bent structure, with a bond angle of 100° and an O–O distance of 119 pm.

1.3. Properties

Oxygen is present in the peroxo group in the comparatively unstable oxidation state -1. Hydrogen peroxide can behave as an oxidizing or reducing agent, depending on the coreactant, with the oxygen gaining or losing electrons to attain the more stable oxidation state -2 or 0. Most inorganic peroxides, however, act predominantly as oxidizing agents.

Another typical property of many peroxo compounds is their ready decomposition to form radicals. The first step is homolytic cleavage of the O–O bond, which can be initiated either thermally or catalytically (e.g., by metal ions). The industrial importance of many organic and inorganic peroxides as polymerization accelerators is based on this behavior.

Another typical reaction is exothermic redox disproportionation. This type of reaction is the cause of the loss of active oxygen on prolonged storage or heating. The decomposition can be suppressed or considerably reduced by adding small quantities of stabilizers such as magnesium sulfate or sodium silicate. Many commercial peroxo compounds stabilized in this way have extremely good storage stability at room temperature. All aqueous solutions of peroxo compounds hydrolyze forming hydrogen peroxide.

The alkali metal hyperoxides are very powerful oxidizing agents and react vigorously with water to form hydroxides with liberation of oxygen. The alkali metal ozonides are unstable and readily decompose to form hyperoxides and oxygen; they also form alkali metal hydroxides and oxygen with water.

1.4. Analysis

The quantitative determination of peroxidic oxygen in peroxo compounds is usually carried out by hydrolysis in aqueous solution to form H_2O_2, followed by titration with permanganate, cerium(IV) sulfate or potassium iodide/thiosulfate, giving the so-called active oxygen content in weight percent. This terminology is historic and is based on the incorrect assumption that one of the oxygen atoms is initially split off from the peroxo group as atomic oxygen. Thus, in 1 mol H_2O_2 (34 g) the active oxygen content is 16 g or 47.06 wt %.

2. Peroxides, Hyperoxides, and Ozonides of the Alkali and Alkaline Earth Metals

2.1. Peroxides

The alkali and alkaline earth metals form peroxides with the general formulae $M_2^IO_2$ and $M^{II}O_2$, respectively, which crystallize with an ionic lattice and contain the diamagnetic O_2^{2-} anion. In the case of lithium and the elements of Group 2 of the periodic table, the preparation can be carried out in aqueous solution from the hydroxides and hydrogen peroxide, but the alkali metal peroxides and also barium peroxide are better produced by oxidation of the metal or metal oxide. All these compounds are colorless or light yellow, the color being caused by small

amounts of the hyperoxides. The alkali and alkaline earth metal peroxides are powerful oxidizing agents that usually have good stability in the pure state if stored with exclusion of moisture. If they come into contact with organic materials or other reductants, there is danger of spontaneous ignition or even explosion.

Most of all these peroxides form many hydrates and peroxohydrates. They dissolve in water exothermically, forming hydrogen peroxide and the hydroxide of the metal. The alkali metal peroxides form compounds with a number of penta- and hexavalent heavy metal, oxides, e.g., of vanadium, molybdenum, tungsten and uranium, with the general formulas $2\,M^{I}_2O_2{\cdot}M^{V}_2O_5$ and $M^{I}_2O_2{\cdot}M^{VI}O_3$ [8].

2.1.1. Sodium Peroxide

Sodium peroxide was produced on a large scale for many years, and was an important raw material in the synthesis of sodium peroxoborates and sodium carbonate peroxohydrate. In the early 1980s, most of the large-scale plants ceased production because the more cost-effective hydrogen peroxide produced by the autoxidation process replaced sodium peroxide in most industrial applications. Today sodium peroxide is used only in small quantities for specialty applications, e.g., as a fusion agent in chemical analysis.

Properties. Sodium peroxide, [*1313-60-6*], Na_2O_2, M_r 78.0, ϱ 2.6 g/cm^3, is a yellowish white powder with a theoretical active oxygen content of 20.5 wt %. It melts at ca. 660 °C and decomposes above 300 °C with liberation of oxygen. The oxygen dissociation pressure is 101.3 kPa (1 atm) [9]. Sodium peroxide is hygroscopic, but in the absence of moisture it exhibits good shelf life.

Sodium peroxide is a powerful oxidizing agent. In contact with organic materials or other reducing agents, spontaneous ignition and even explosion can occur. Sodium peroxide dissolves exothermically in water to form sodium hydroxide and hydrogen peroxide. Sodium peroxide reacts with hydrogen gas yielding sodium hydroxide [10].

Sodium peroxide forms several peroxohydrates and hydrates, namely: $Na_2O_2 \cdot 2\,H_2O_2$, $Na_2O_2 \cdot 2\,H_2O_2 \cdot 4\,H_2O$, $Na_2O_2 \cdot 2\,H_2O$, and $Na_2O_2 \cdot 8\,H_2O$ [8].

In Europe sodium peroxide is manufactured by Meteaux Speciaux in France.

Production. Gay-Lussac and Thenard first prepared sodium peroxide in 1811 by the combustion of sodium metal. This method formed the basis for the large-scale production of this compound. The oxidation to sodium peroxide takes place with intermediate formation of sodium oxide:

$$2\,Na + 1/2\,O_2 \rightarrow Na_2O \quad \Delta H = -431.6\,kJ/mol$$
$$Na_2O + 1/2\,O_2 \rightarrow Na_2O_2 \quad \Delta H = -79.6\,kJ/mol$$

The first industrial process for the manufacture of sodium peroxide was the block process, developed by Castner in 1891 and operated by Degussa in Rheinfelden since 1899, and later developed in several stages to give the classical continuous rotary furnace process [11]. Another continuous process which has long been in use is the U.S. Industrial Chemicals Process (USI Process) [12].

Rotary Furnace Process (Fig. 1). The sodium is oxidized in two stages. In the first stage, molten sodium is continuously fed countercurrently with an excess of dry air into a rotary furnace (the combustion furnace, b), which contains previously formed sodium oxide in powder form. The furnace rotates at ca. 2 rpm and is cooled externally with water because of the exothermic reaction. The reactor temperature is 600–700 °C near the entry point of the sodium, falling to 150–200 °C at the discharge end. The sodium oxide leaving the rotary furnace contains a few percent sodium peroxide and a maximum of 1 % of sodium metal. After intermediate storage in a bunker (e), it is fed by a screw conveyor or traveling containers via a lock to the next stage for further oxidation in a rotary reactor lined with sheet nickel (f). Because of the low exothermicity of the peroxide formation, this reactor is located in a brick-lined muffle furnace heated by gas or oil; it rotates at about the same speed as the combustion furnace. The oxidizing agent is oxygen from an air separation plant, which is introduced in cocurrent flow with the sodium oxide. It is important to maintain the reaction temperature at the optimum value of 350–400 °C, otherwise the product can stick on

Figure 1. Production of sodium peroxide by the rotary furnace process

the reactor wall and lose its free-flowing properties. After leaving the reactor, the sodium peroxide is cooled and then screened into the various particle size fractions. The product consists of small pale yellow spheres with a sodium peroxide content of ca. 99 %. The off-gases from the two furnaces are purified by scrubbers (c, g) and a separator (d).

USI Process [12]. In the USI process, like the rotary furnace process, sodium oxide is produced in the first stage by reaction of sodium metal with recycled off-spec sodium peroxide. The reactants are mixed at ca. 120 °C in a nitrogen atmosphere and then heated in a reactor at > 250 °C. Since excess sodium peroxide is used, a mixture of sodium peroxide and sodium oxide is obtained. This is oxidized by air in a heated rotary furnace to form the peroxide. The product is classified, and the fine and coarse material recirculated to the first stage. Since the process is operated exclusively with air as the oxidizing agent, 80–90 % of the peroxide formed must be recycled.

2.1.2. Other Peroxides

Lithium peroxide [*12031-80-0*], Li_2O_2, M_r 45.9, ϱ 2.36 g/cm^3, has good thermal stability and, unlike Na_2O_2, is not hygroscopic. The theoretical active oxygen content is 34.8 wt %, which is the highest of all metal peroxides. It has not attained industrial importance due to the comparatively high cost of lithium and its compounds and high manufacturing costs, among other reasons.

Lithium peroxide can be produced by the reaction of dilute aqueous solutions of lithium hydroxide with 30 wt % hydrogen peroxide to form lithium peroxide monoperoxohydrate trihydrate ($Li_2O_2 \cdot H_2O_2 \cdot 3\ H_2O$), which is then dehydrated over phosphorus pentoxide or under vacuum [13]. Other methods include the reaction of lithium alkoxides in alcoholic solution with concentrated hydrogen peroxide [14], and the treatment of solid lithium oxide hydrate with concentrated hydrogen peroxide, followed by washing the precipitate with methanol and drying in a conveying dryer [15]. Another process has been proposed in which hydrogen peroxide and saturated lithium hydroxide solution are sprayed together into a spray dryer [15].

Calcium and Strontium Peroxides. Calcium peroxide [*1305-79-9*], CaO_2, M_r 72.1, ϱ 2.92 g/cm^3, theoretical active oxygen content 22.2 wt %, and strontium peroxide [*1314-18-7*], SrO_2, M_r 119.6, ϱ 4.7 g/cm^3, theoretical active oxygen content 13.4 wt %, are produced by precipitation of the octahydrate from an aqueous solution of a salt or hydroxide, followed by dehydration at temperatures above 100 °C [16]. The thermal stability of strontium peroxide (decomp. ca. 410 °C) is marginally higher than that of calcium peroxide (decomp. ca. 375 °C). The active

oxygen content of the commercial products is only 60–90 % of the theoretical value. Calcium peroxide is sold under the trade name PermeOx by FMC. Calcium peroxide is also manufactured by Solvay.

Calcium peroxide is used as oxygen source in the leaching of gold and silver ores with cyanide to improve precious metal recovery and leaching kinetics [17]. A relatively new application for CaO_2 is as a peroxide source in toothpaste [18] and dental chewing gum products. Calcium peroxide is also used in limited quantities as a hardening accelerator for sulfide rubber, as dough conditioner in the baking industry, and as a nontoxic disinfectant for seed and grain [19 – 21].

Strontium peroxide is used in pyrotechnics and tracer bullet formulations.

Barium peroxide [*1304-29-6*], BaO_2, M_r 169.4, ϱ 5.4 g/cm^3, theoretical active oxygen content 9.4 wt %, was the earliest known peroxo compound. It was used until the mid-1900s as the starting material for the production of hydrogen peroxide by the Thenard reaction [22].

Barium peroxide is the only peroxide of the Group 2 metals that can be prepared at atmospheric pressure by air oxidation of the oxide. Air is passed over finely spread barium oxide at 500–550 °C. On further heating in air to ca. 700 °C, oxygen is liberated [23]. On the industrial scale, barium peroxide is produced in a rotary furnace in the presence of a small quantity of steam to accelerate the reaction. Today barium peroxide has only limited application in the manufacture of fireworks.

Magnesium and Zinc Peroxides. Magnesium peroxide [*14452-57-4*], MgO_2, M_r 56.3, and zinc peroxide [*1314-22-3*], ZnO_2, M_r 97.3, are manufactured in the same way as calcium and strontium peroxides [24]. However, well-defined compounds are not obtained, but mixtures of peroxohydrates and hydroxides with a peroxide content between 25 and 50 wt %. Zinc peroxide is used in dusting powders, as a deodorant, and in pharmacology for the treatment of infections and skin lesions. Recently, magnesium peroxide has been promoted as a oxygen-release compound for soil remediation [25]. Producers of magnesium peroxide are Solvay, Regenesis and FMC.

2.2. Hyperoxides

Hyperoxides, which are derived from the unstable HO_2 radical, have been described for some of the highly electropositive alkali and alkaline earth metals [26, 27]. Only potassium hyperoxide has a limited commercial importance.

Potassium hyperoxide [*12030-88-5*], KO_2, M_r 71.1, ϱ 2.14 g/cm^3, is a paramagnetic yellow solid for which melting points between 380 °C and 440 °C have been reported [30]. The physical properties of KO_2 are summarized in [28, 29]. It is used as an oxygen generator and carbon dioxide absorber in breathing apparatus and gas masks. This application is based on the ability of potassium hyperoxide to simultaneously give off oxygen and absorb carbon dioxide in the presence of water vapor. The following reactions take place above 20 °C:

$$4\,KO_2 + H_2O \rightarrow 2\,KOH + 3\,O_2$$

$$2\,KOH + CO_2 \rightarrow K_2CO_3 + H_2O$$

Figure 2. Production of potassium peroxide
a) Molten salt vessel; b) Spray nozzle; c) Reactor; d) Receiving vessel; e) Cyclone

Potassium hyperoxide can be prepared from potassium hydroxide and concentrated hydrogen peroxide, which are allowed to react under cooling at reduced pressure to give potassium

Table 1. The sodium peroxoborates

Common name	CAS registry no.	Historical formula	IUPAC name and constitutional formula
Sodium peroxoborate hexahydrate	[*10486-00-7*]	$NaBO_2 \cdot H_2O_2 \cdot 3\,H_2O$	disodium di-μ-peroxo-bis(dihydroxoborate) hexahydrate
Sodium perborate tetrahydrate	[*13517-20-9*]	$NaBO_3 \cdot 4\,H_2O$	Sodium peroxoborate trihydrate	[*28962-65-4*]	$NaBO_2 \cdot H_2O_2 \cdot 2\,H_2O$	disodium di-μ-peroxo-bis(dihydroxoborate) tetrahydrate
Sodium perborate trihydrate	[*28108-09-0*]	$NaBO_3 \cdot 3\,H_2O$	Sodium peroxoborate monohydrate	[*10332-33-9*]	$NaBO_2 \cdot H_2O_2$	disodium di-μ-peroxo-bis(dihydroxoborate)
Sodium perborate monohydrate	[*15120-21-5*]	$NaBO_3 \cdot H_2O$	Anhydrous sodium peroxoborate	[*7632-04-4*]	$NaBO_3$	not a well-defined compound; sodium borate/boron–oxygen radical

peroxide diperoxohydrate $K_2O_2 \cdot 2\,H_2O_2$ [31, 32]. It decomposes at elevated temperature to form KO_2 (dehydration in a vacuum or spray drying). Another industrial process [33] uses potassium metal as the starting material (Fig. 2). Molten potassium is sprayed into a closed reactor (c) where it reacts with a large excess of preheated air at ca. 75 °C. The reaction is highly exothermic, and the temperature in the reactor reaches ca. 300 °C. The powdered product is removed by a screw conveyor and is then granulated.

KO_2 is manufactured by Mine Safety Appliance Company (USA).

2.3. Ozonides

Ozonides of the alkali metals with the general formula M^IO_3, can, with the exception of lithium ozonide, be prepared by the reaction of ozone–oxygen mixtures with the solid hydroxide, or preferably the hyperoxide, of the metal. These compounds are dark in color and paramagnetic. They are not very stable; the stability increases with increasing atomic mass of the metal. They decompose readily into the hyperoxide and oxygen [2]. Ozonides have no industrial importance.

3. Peroxoborates

3.1. Sodium Peroxoborates

3.1.1. Properties

Sodium peroxoborate exists as the hexahydrate, the tetrahydrate, the trihydrate, the water-of-crystallization-free substance, and the anhydrous substance. Anhydrous sodium perborate (trade name: Oxoborate) is not a peroxoborate compound. The naming of the sodium peroxoborates has long been confused. Table 1 lists the trivial names and systematic IUPAC nomenclature, CAS numbers, formulas, and molecular structures of the sodium peroxoborates and anhydrous sodium perborate. Most commonly used in the detergent industry are the names sodium perborate tetrahydrate and sodium perborate monohydrate. Sodium perborate trihydrate has no industrial importance.

Sodium perborate tetrahydrate was first prepared in 1898 by Tanatar and by Melikoff and Pissarjewski by the action of hydrogen peroxide on a solution of borax and sodium hydroxide [34]. The long-running controversy as to whether this is a peroxo salt or an addition compound of H_2O_2 was ultimately resolved by Hansson in 1961 by a single-crystal X-ray structure analysis [35].

The molecular structure (Fig. 3) consists of dimeric $[(HO)_2BOO]^-$ units, which form cen-

Figure 3. A) Part of the chain of hydrated Na^+ ions in sodium peroxoborate tetrahydrate; B) Structure of the $[BO_2(OH)_2]_2^{2-}$ anion

trosymmetric cyclic anions with two peroxo bridges. The sodium cations are coordinated by the water of crystallization and by certain hydroxide groups of the six-membered ring. The anions and cations form a polymeric structure.

An X-ray structural analysis of sodium perborate trihydrate [36], together with physicochemical investigations of the monohydrate, has shown that these compounds also contain the above-mentioned six-membered ring structure [37]. A molecular structure for the anhydride has been discussed in which the six-membered ring is a boron–oxygen radical [38].

Vapor-pressure studies on sodium perborate hydrates [26] have shown that the isotherms for compound formation and decomposition as a function of water vapor partial pressure exhibit marked hysteresis; that is, the sodium perborate hydrates do not behave as classical hydrates, for which the formation and decomposition reactions are reversible.

The thermal decomposition of sodium perborate hydrates has been investigated by thermogravimetric analysis. The decomposition curves for the tetrahydrate and trihydrate are very similar. At temperatures above 150 °C they corre-

spond to the curve obtained with sodium perborate monohydrate [37].

Physical Properties.

Sodium perborate tetrahydrate, M_r 153.9, ϱ 1.731 g/cm^3, theoretical active oxygen content 10.38 wt %, melts in its own water of crystallization at 65.5 °C.

The commercial product is a white, crystalline solid with a spherolitic or elongated particle shape, and a particle size distribution of 0.1–1.0 mm. Depending on the crystal shape, bulk densities of 0.65–0.9 kg/L can be obtained. When stored under cool, dry conditions the rate of loss of active oxygen is only 1 % per year. Decomposition is accelerated at higher temperatures and moisture content. There is a tendency for increased caking at higher temperatures caused by conversion of the tetrahydrate to the trihydrate [39].

The solubility in water is 0.152 mol/L at 20 °C and 0.388 mol/L at 40 °C.

Thermogravimetric analysis curves for sodium perborate tetrahydrate show that decomposition takes place in three stages: 20–150 °C, 150–165 °C, and 165–400 °C. In the first stage, the tetrahydrate is dehydrated to the monohydrate.

Sodium perborate trihydrate, M_r 135.9, ϱ 1.86 g/cm^3, theoretical active oxygen content 11.8 wt %, melts in its own water of crystallization at 81.7 °C.

Solubility and vapor pressure determinations indicate that above 15 °C sodium perborate trihydrate is the thermodynamically more stable phase. The tetrahydrate is stable below this temperature. However, the transition requires considerable activation energy and therefore only occurs in solution at elevated temperature or upon addition of substances which reduce the solubility [40].

Sodium perborate monohydrate, M_r 99.8, has a theoretical active oxygen content of 16.0 wt %. The anhydrous compound has no definite melting point and decomposes when strongly heated, liberating water and oxygen. The commercial product is manufactured by dehydration of sodium perborate tetrahydrate and is a white crystalline solid with a bulk density of 0.5–0.65 g/cm^3, depending on the starting material used. Modern methods of direct synthesis give a product with a bulk density between 0.4 and 1 g/cm^3 [41, 42]. A major advantage of sodium perborate monohydrate compared to the tetrahydrate, apart from its higher active oxygen content, is its much higher rate of dissolution, which results in better bleaching performance under short wash cycle conditions. The time required for 2 g tetrahydrate to dissolve in 1 L water at 15 °C is 6–8 min, while the same amount of monohydrate dissolves in < 1 min.

Anhydrous sodium perborate, also known under the trade name Oxoborate, has a theoretical molecular mass of 81.8. However, the commercial product is heterogeneous and contains ca. 2 wt % residual active oxygen. The releasable oxygen is liberated spontaneously as molecular oxygen when anhydrous sodium perborate comes into contact with water.

The releasable oxygen is determined by adding a weighed amount to dilute sulfuric acid, and measuring the oxygen liberated either gravimetrically or volumetrically. Oxoborate has a pale yellowish color. It is X-ray amorphous, and has paramagnetic properties [43].

Chemical Properties. Cryoscopic molecular mass determinations and conductivity measurements show that in aqueous solution the sodium perborate hydrates are partially hydrolyzed, reforming the starting materials metaborate and hydrogen peroxide according to the following equation [37]:

As can be seen from this equation, the amount of free H_2O_2 cannot be determined by titration, since this continually displaces the equilibrium.

The aqueous solution of sodium perborate reacts like an alkaline solution of hydrogen peroxide, the active oxygen content being catalytically decomposed by heavy metal ions. Stabilization can be achieved by adding magnesium salts. The pH is 10.1–10.4 and is virtually independent of the concentration. The active oxygen content can be determined by titration with potassium permanganate in dilute sulfuric acid. The sodium content is measured by titration with hydrochloric acid using methyl orange as the indicator. Finally, the boron content is determined by reacting the solution with a polyhydric alco-

hol, e.g., glycerine, leading to complex formation and producing a monobasic acid which can be titrated with sodium hydroxide solution using phenolphthalein as the indicator.

3.1.2. Production

The former electrochemical production of sodium perborate tetrahydrate is no longer of commercial importance [44]. The demand for higher product quality has led to the development of the process described below, almost the only one used today on a large scale.

Raw Materials. The boron-containing raw material is generally a water-soluble sodium tetraborate. Technical-grade borax pentahydrate is used, but impure minerals such as kernite and tincal are also employed.

The minerals ulexite (sodium calcium borate), colemanite and pandernite (calcium borates) are also used but to a lesser extent because they must be reacted with sodium carbonate, producing considerable quantities of sludge. The active oxygen component is usually hydrogen peroxide.

Sodium perborate tetrahydrate is produced in a two-stage process (Fig. 4). In the first stage, the boron minerals are reacted with aqueous sodium hydroxide to yield a highly concentrated solution of sodium tetrahydroxoborate:

$$Na_2B_4O_7 + 2\,NaOH + 7\,H_2O \rightarrow 4\,NaB(OH)_4$$

Recycled mother liquor from the crystallization stage is mixed with sodium hydroxide solution and the boron-containing raw material added, whereby the temperature rises from 60 to 95 °C [45]. Insoluble components are then removed by decantation or filtration. The resulting clear solution containing up to 800 g/L solid (expressed as $NaBO_2$) is diluted with more recirculated mother liquor and is subsequently cooled to below 40 °C. In the second stage, the diluted solution of sodium tetrahydroxoborate is treated with hydrogen peroxide with cooling at temperatures below 30 °C. This causes sodium perborate tetrahydrate to precipitate:

$$2\,NaB(OH)_4 + 2\,H_2O_2 + 2\,H_2O \rightarrow Na_2\left[BO_2(OH)_2\right]_2 \cdot 6\,H_2O$$

The perborate is stabilized by adding a solution of magnesium sulfate or alkali metal or alkaline earth metal silicate, either before or after the crystallization stage [46].

Both the chemical reaction and the crystallization can have several variations. The two components can be reacted continuously in the crystal-free external recirculation zone of a vacuum crystallizer, and then caused to flow through the salt layer, so that the solution is no longer supersaturated [47]. Depending on the raw materials used and the process, different crystal shapes and crystal size distributions can be obtained.

Figure 4. Flow diagram for the production of sodium peroxoborate

Degussa has described a process for the production of attrition-resistant sodium perborate tetrahydrate crystals. A highly supersaturated solution (200–700 g/L) of sodium perborate is passed into a previously prepared suspension of small crystals. Crystallization initiated by these nuclei yields coarse, compact crystal agglomerates [48].

Kali-Chemie has reported a continuous process in which controlling the stoichiometry produces attrition-resistant, free-flowing crystals of sodium perborate tetrahydrate with a bulk density of 0.75–0.85 kg/L [49]. Crystallization is carried out in an open, cooled, stirred vessel. The sodium perborate suspension formed is continuously removed and fed at a controlled rate directly into an automatic centrifuge. The mother liquor is recirculated. The separated crystals, containing 3–10 wt % water, are dried in a rotary or fluidized-bed dryer with air at ca. 100 °C [49].

During drying, the temperature of the salt must be kept below 60 °C to prevent melting. After drying, the product is cooled to ca. 25 °C by air in fluidized-bed coolers. Fine particles of perborate are removed from the exhaust air by wet scrubbers, integrated in the mother liquor recirculation system.

Major producers of sodium perborate tetrahydrate are Belinka (Slowenia), Degussa (Belgium, Austria), Etibank (Turkey), FMC Foret (Spain), Solvay (Australia, Germany).

Sodium perborate monohydrate is produced by dehydration of sodium perborate tetrahydrate. By removing the water of crystallization with warm air in a fluidized-bed dryer, an attrition-resistant product is obtained. The inlet temperature of the air is maintained between 180 and 210 °C [50].

A highly attrition resistant product is obtained by dehydration under vacuum [51], or in a fluidized-bed dryer operating at a relative humidity of 10–40 % and an air inlet temperature of 100–180 °C [52]. Alternatively a relative humidity of 40–80 % and an air exhaust temperature of at least 60 °C can be employed [53]. Besides the conventional processes with tetrahydrate as an intermediate, new production technologies have been described in which sodium perborate monohydrate is produced directly from aqueous solutions.

According to an Interox patent, attrition-resistant granules of sodium perborate monohydrate with a bulk density of 0.4–1 kg/L are obtained by spraying solutions of H_2O_2 and $NaBO_2$ onto a fluidized bed of crystal nuclei at up to 100 °C [42]. The rate of dissolution of these granules is rather low compared to that of monohydrate manufactured by conventional processes but can be improved by adding surface-active agents [54].

Degussa has described the direct synthesis of a sodium perborate monohydrate product with a bulk density of 0.4–1 kg/L. Sodium perborate solution is spray-dried to produce the monohydrate in the form of a fine powder. The fines are then granulated in a fluidized bed or granulated by compression to yield a product with good storage stability and dissolution properties [41].

Major producers of sodium perborate monohydrate are Degussa (Belgium, Austria), FMC Foret (Spain), Solvay (Germany).

Anhydrous sodium perborate is produced by further dehydration of sodium perborate monohydrate. Sodium perborate monohydrate is dehydrated in a fluidized bed with dry air at 150–160 °C [56]. The dehydration of the tetrahydrate requires a stepwise, slow temperature increase using dry, CO_2-free air to avoid agglomeration of the particles in the fluidized bed [57]. Both processes yield products with 15–17 wt % releasable oxygen and 1–2 wt % active oxygen.

3.1.3. Uses

Sodium perborate tetrahydrate and monohydrate are still used with decreasing tendency as active oxygen source in oxidizing and bleaching agents in cleaning, cosmetic, and pharmaceutical products, but mainly in detergents (→ Laundry Detergents). It is estimated that ca. 95 % of the perborates are consumed by this market. Detergents contain up to 30 wt % sodium perborate tetrahydrate and/or up to 15 wt % monohydrate. The monohydrate is preferred if rapid dissolution, improved storage stability, and compatibility with other constituents such as activators and water-softening agents are required. Other applications include detergents for automatic dishwashers, denture cleaners, color-safe bleach powders, and hair-treatment prepa-

rations. Sodium perborate has been used as a slow-release oxygen source in heap leaching of gold and silver ores [55].

Anhydrous sodium perborate is mainly used in denture cleanser tablets to enhance dissolution and to produce effervescence.

In 1998 the world production capacity for perborates (as sodium perborate tetrahydrate) was estimated at 550 000 t of which approximately 85 % was produced in Europe. With changes in European environmental policy and the discussion on the ecotoxicological properties of borates and perborates at the end of the 20th century, a continuous shift from sodium perborates to sodium carbonate peroxohydrate took place, and this entailed a significant reduction in production capacity estimated in 2004 to be less than 300 000 t. Especially Solvay converted existing sodium perborate production facilities to sodium carbonate peroxohydrate production.

3.1.4. Product Specifications

Commercial sodium perborate tetrahydrate and monohydrate have an active oxygen content of at least 10 and 15 wt %, respectively. They are white, odorless, free-flowing salts with a particle size distribution of 95 % between 0.1 and 1.0 mm. Modifications in the production process can give bulk densities for the tetrahydrate between 0.65 and 0.85 kg/L, and for the monohydrate between 0.50 and 0.65 kg/L. With storage under cool, dry conditions, the annual active oxygen loss rate is $< 2\,\%$ (relative). The dissolution time for 2 g substance in 1 L water is ca. 6–8 min for the tetrahydrate and < 1 min for the monohydrate. The residual moisture content, determined by drying for 30 min at 60 °C in a vacuum, should not exceed 1 wt % for the monohydrate. Attrition resistance is an important parameter and should not be higher than 10 % according to ISO 5937.

Commercial anhydrous sodium perborate has at least 13.0 wt % releasable oxygen and ca. 1.5–2.5 wt % active oxygen. It also contains small amounts of sodium perborate monohydrate and sodium metaborate, depending on the production process. The light yellow salt has a particle size distribution of ca. 90 wt % between 0.1 and 1.0 mm and a bulk density between 0.3 and 0.4 kg/L. It dissolves readily in water with evolution of oxygen.

3.1.5. Storage and Transportation

Sodium perborates must be stored under cool, dry conditions. Exothermic decomposition with liberation of oxygen can be caused by heat, moisture, and/or contact with decomposition catalysts, e.g., heavy metals, alkali, or dirt. Adiabatic storage conditions can lead to self-accelerating decomposition of sodium perborate monohydrate.

After manufacture, sodium perborate tetrahydrate and monohydrate may be stored in silos and transported in bulk by rail or truck or packed in paper sacks, optionally with polyethylene inner liners, or in polyethylene sacks. Oxoborate (anhydrous sodium perborate) is transported only in polyethylene-lined paper sacks.

Sodium perborate tetrahydrate is considered nonhazardous for international transportation purposes. Due to a change in testing methods for oxidizing substances, the UN classification for sodium perborate monohydrate changed recently to Oxidizer 5.1. [59]. Oxoborate has been assigned UN No. 3247 and is also classified as a Class 5.1 oxidizing substance.

3.2. Other Peroxoborates

Melikoff and Pissarjewski prepared peroxoborates of magnesium, calcium, barium, and strontium in 1898. Production processes for potassium peroxoborate [58, 60] and the peroxoborates of the alkaline earth metals have been described in patents [61]. Novel peroxoborates with monovalent cations and considerable molar excess of H_2O_2 have been published by Heller and Pawel [62]. However, these compounds now have no commercial importance.

4. Peroxosulfuric Acids and Peroxosulfates

Peroxomonosulfuric acid and peroxodisulfuric acid are intermediates in the former electrochemical production of hydrogen peroxide (→ Hydrogen Peroxide, Section 4.3). Peroxodisulfuric acid is not of commercial importance.

However, its salts, the peroxodisulfates, are widely used as active oxygen carriers and oxidizing agents. Industrially important salts of peroxodisulfuric acid are those of ammonium [*7727-54-0*], sodium [*7775-27-1*], and potassium [*7727-21-1*].

Peroxomonosulfuric H_2SO_5 in the form of Caro's acid has found industrial applications in the mining industry and in pulp bleaching. The salts of peroxomonosulfuric acid include the peroxomonosulfates of the alkali, alkaline earth, and other metals [63], e.g., $KHSO_5$ [*25482-78-4*] [64], and the triple salt $2\ KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$ [*37222-66-5*] [65], which is sold under the trade names Caroat (Degussa) and Oxone (DuPont).

4.1. Peroxomonosulfuric Acid

Peroxomonosulfuric acid [*7722-86-3*] is a colorless crystalline solid, *mp* 45 °C, that is difficult to prepare in high purity. Solutions of Caro's acid lose active oxygen significantly faster than hydrogen peroxide solutions. The stability of peroxomonosulfuric acid solutions increases with decreasing concentration and residual H_2O_2 content [66]. Peroxomonosulfuric acid is a strong acid. The proton bound to the peroxo group is, like that in H_2O_2, a weak acid with a pK_a of 9.4. In the presence of water it hydrolyzes rapidly yielding H_2O_2 and sulfuric acid.

Peroxomonosulfuric acid is a powerful oxidizing agent:

$$H_2SO_5 + 2\,H^+ + 2\,e^- \rightarrow H_2SO_4 + H_2O \quad E^\circ = -1.81\ V$$

The oxidation potential of peroxomonosulfuric acid was determined by a thermodynamic method to be 1.81 V [67, 68]. It oxidizes cyanide to cyanate, chloride to chlorine, sulfide to sulfate, and formaldehyde to H_2 and formic acid. Under neutral and alkaline conditions, peroxomonosulfate oxidizes hydrogen peroxide yielding oxygen gas. Peroxomonosulfuric acid exhibits significantly better bactericidal properties than H_2O_2 and has good overall effectiveness against bacteria and viruses, in particular under weakly acidic conditions [69].

4.2. Caro's Acid

Caro's acid is named after Heinrich Caro (1834–1910) who first described its synthesis and properties in 1898.

Production. Caro's acid obtained by treating sulfuric acid with hydrogen peroxide is an equilibrium mixture of peroxomonosulfuric acid, hydrogen peroxide, sulfuric acid, and water. The equilibrium constant for this reaction is 0.1 [70].

$$H_2O_2 + H_2SO_4 \rightleftharpoons H_2SO_5 + H_2O$$

The highly exothermic reaction requires removal of the heat of reaction to give high yields of peroxomonosulfuric acid. There are two manufacturing technologies: the isothermal and the adiabatic process.

In the *isothermal process*, 70 % H_2O_2 is mixed with 93–98 % sulfuric acid with efficient heat removal, so that the temperature does not exceed 15–30 °C. If equimolar quantities of reactants are employed, the product contains 42–50 % H_2SO_5 and ca. 10 % H_2O_2. H_2SO_5 yields can be significantly increased by increasing the amount of H_2SO_4 or by using oleum. Degussa describes an on-site manufacturing process in which H_2O_2 is added in separate reaction stages in series resulting in ca. 15 % higher yields over conventional single-stage reactors when a 2:1 molar ratio of H_2SO_4 (96–98 %) and H_2O_2 (70 %) is employed [71, 72].

In the *adiabatic process*, the reactants are mixed rapidly in a small-volume, high-throughput static mixer without cooling. Several patents describe various designs of equipment for adiabatic generation of Caro's acid [73 – 77]. Typically, the yields of Caro's acid with this method are in the range of 25–45 %. A process for the production of stable aqueous sodium peroxomonosulfate solutions has been described by Degussa [66].

Uses. Due to new and cost-effective on-site generation technologies, Caro's acid has found increasing use in mining and hydrometallurgy, pulp bleaching, and the electronics industry.

In the mining industry, Caro's acid is used as a detoxifying agent for residual cyanide in the tailings from gold and silver ore processing. Due to its faster oxidation kinetics and oxidizing power, Caro's acid has several advantages over

Figure 5. Arrangement of the complex anions in the compound 2 $KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$

catalyzed H_2O_2 (e.g., it also oxidizes thiocyanate). This application is practiced at several gold mines in North America [78 – 82]. Caro's acid also has been described as an oxidant in uranium ore processing.

In the pulp and paper industry, Caro's acid has proved to be an effective delignification chemical in totally chlorine free bleaching sequences; it replaces chlorine and chlorine dioxide. When employed under controlled pH and temperature conditions, the mechanical properties of the cellulose fibers are not impaired [83 – 86]. DuPont describes a delignification process using a combination of Caro's acid and peracetic acid [87, 88]. Caro's acid is also the starting material for the manufacture of peroxomonosulfates (see Section 4.3.2).

A proprietary form of Caro's acid is marketed in the electronics industry under the name of Nanostrip. It is used for cleaning and reclaiming of silicon wafers. Manufacturers are Cyantech (US), Micro-Image Technologies (UK), and RASA Industries (Japan).

4.3. Peroxomonosulfates

4.3.1. Properties

A number of sodium, potassium, ammonium, cesium, lithium, and rubidium salts of peroxomonosulfuric acid have been described in the literature. Only the potassium salt in the form of the triple salt 2 $KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$, M_r 614.8, ϱ 2.313 g/cm^3, theoretical active oxygen content 5.2 wt %, has gained commercial importance. Recent X-ray structure analysis investigations [89] have shown that it crystallizes in the monoclinic system, contrary to earlier reports describing an orthorhombic structure [65]. The crystal lattice consists of an array of K^+ cations and $H_3S_4O_{18}^{5-}$ anions in which HSO_5^-, HSO_4^- and SO_4^{2-} units are also included (Fig. 5).

The commercial product is a white, odorless, free-flowing material with a bulk density of 1–1.2 kg/L. About 90 wt % is in the particle size range 0.1–0.8 mm. Under proper storage conditions, the loss of active oxygen is < 1 % per month. The triple salt is soluble in water (25 g/L H_2O at 20 °C) and dissolves rapidly. The pH of an 1 wt % solution is ca. 2.3. The bactericidal properties of the triple salt are summarized in [90].

The triple salt is classified by the UN as corrosive solid under UN No. 3260.

4.3.2. Production

The starting materials are sulfuric acid or oleum, hydrogen peroxide, and potassium hydroxide. In the first step, hydrogen peroxide (65–90 wt %) and oleum (53–82 wt %) in a molar ratio of 1:1.3–2.7 are continuously mixed in a cooled reaction vessel at a temperature below 8 °C to obtain a 37–66 wt % peroxomonosulfuric acid containing H_2SO_4, H_2O, and H_2O_2 [91].

In the second stage the mixture is partially neutralized with potassium hydroxide and the triple salt is crystallized. This step requires careful control of the mother liquor composition to obtain high yields [65] (see Fig. 6).

Figure 6. Region of stability of the triple salt 2 $KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$ as a function of the composition of the mother liquor and temperature

According to a patent of the former Peroxid-Chemie (today Degussa), peroxomonosulfuric acid is produced from H_2SO_4 (90–100 wt %) and H_2O_2 (30–90 wt %), and then continuously fed, together with a concentrated solution of potassium hydroxide, into a circulating mother liquor containing 25–30 wt % $KHSO_5$ and ca. 15 wt % H_2SO_4 or K_2SO_4 in aqueous solution [92]. The water introduced with the raw materials and formed in the neutralization reaction is removed by passing the reaction mixture through vacuum treatment equipment at ca. 25 °C and 1 kPa. Some of the circulating liquor is continuously removed and cooled to ca. 5 °C in a crystallizing vessel, resulting in precipitation of the triple salt.

The salt is isolated by centrifugation, and the mother liquor is fed back into the circulating solution. The filter cake is washed while in the centrifuge, and the wet salt is dried in a fluidized-bed dryer [92]. The product is packed in polyethylene-lined plastic sacks and is stored under cool, dry conditions.

4.3.3. Uses

Peroxomonosulfate triple salt is used because of its powerful oxidizing properties and bactericidal effects in surface cleaners and dishwashing powders to improve bleaching and disinfecting action, especially at low temperatures [93 – 95]. Ketones have been reported to enhance the bleaching power of peroxomonosulfates by in situ formation of highly reactive dioxiranes [96 – 98].

A major use of the triple salt is in denture cleaners. In combination with sodium perborate monohydrate it gives an effervescence due to reaction with perborate yielding oxygen gas under alkaline conditions. In more recent formulations of denture cleaners Caroat is also combined with sodium percarbonate instead of sodium perborate monohydrate. The triple salt is used in the textile industry for nonshrinking and nonfelting treatment of wool, and in the electrical industry for etching printed circuits. In the electroplating and metal finishing industry, potassium peroxomonosulfate triple salt is employed for the treatment of cyanide-containing industrial wastewater and as a mild etchant and pickling agent [99, 100].

In water treatment it has found application as a shock treatment agent for swimming pool water [101]. It quickly oxidizes malodorous chloramines to nitrogen and nitrate.

Another application is its use in wastepaper recycling for destruction of wet-strength resin [102].

4.3.4. Analysis

Peroxomonosulfuric acid can be determined in the presence of H_2O_2 and peroxodisulfuric acid by redox titration, based on the reaction of the H_2SO_5 with arsenic acid and subsequent titration of the residual H_2O_2 with cerium(IV) sulfate solution. The peroxodisulfuric acid is determined by the addition of arsenic acid and ICl and

titration of excess arsenic acid with $Ce(SO_4)_2$ [103].

5. Peroxodisulfuric Acid and Peroxodisulfates

5.1. Properties

The dibasic peroxodisulfuric acid [*13445-49-3*] also known as Marshall's acid, HO_3SOOSO_3H, forms white crystals (*mp* 65°C decomp.).

The hydrolysis of peroxodisulfuric acid to sulfuric acid and peroxomonosulfuric acid is irreversible, while further hydrolysis of peroxomonosulfuric acid is reversible:

$$H_2S_2O_8 + H_2O \rightarrow H_2SO_4 + H_2SO_5$$

$$H_2SO_5 + H_2O \rightleftharpoons H_2SO_4 + H_2O_2$$

The hydrolysis of peroxodisulfuric acid is favored by increasing temperature and acid concentration [104 – 107]. Sulfate radicals are postulated as an unstable intermediate [108]. The peroxodisulfate ion in aqueous solution is one of the most powerful oxidizing agents (E^0 = 2.05 V) [109].

The peroxodisulfates of ammonium, sodium, and potassium are white, crystalline, and stable under dry conditions. The salts decompose on heating in two steps: first the formation of pyrosulfates and oxygen and then upon further heating the decomposition of the pyrosulfate into sulfate and sulfur tri- and dioxide [110, 111]. The decomposition temperatures increase in the series $NH_4^+ < K^+ < Na^+$, and decrease with increasing moisture content. Mixtures with combustible materials are easily ignited and burn vigorously even in the absence of oxygen.

In aqueous solution, the salts are hydrolyzed in a similar manner to peroxodisulfuric acid. Aqueous solutions of peroxodisulfates are slightly acidic (25 wt % $(NH_4)_2S_2O_8$, pH 2.30; 25 wt % $Na_2S_2O_8$, pH 4.35). Solubilities at 20 °C in 100 cm^3 water are: ammonium peroxodisulfate 55.9 g, sodium peroxodisulfate 55.6 g, and potassium peroxodisulfate 5.0 g.

5.2. Production

Pure peroxodisulfuric acid is formed under the same conditions as peroxomonosulfuric acid, i.e., from chlorosulfuric acid and hydrogen peroxide [112]. It has no industrial application.

Aqueous solutions of peroxodisulfuric acid are manufactured by anodic oxidation of sulfuric acid:

$$2\,HSO_4^- - 2\,e^- \rightarrow S_2O_8^{2-} + 2\,H^+ \quad E^0 = 2.057\,V$$

$$2\,SO_4^{2-} - 2\,e^- \rightarrow S_2O_8^{2-} \quad E^0 = 1.939\,V$$

This electrochemical synthesis followed by hydrolysis was formerly the most important industrial manufacturing method for hydrogen peroxide before the development of the autoxidation process.

The electrode process to form $S_2O_8^{2-}$ is complex [113, 114] and is accompanied by the undesired evolution of oxygen. To minimize the evolution of oxygen, electrolysis is performed at high current densities [115] with electrodes having a high oxygen overpotential, e.g., platinum. In addition, potential-increasing substances, e.g., halides or pseudohalides, are added to the electrolyte [116, 117]. The most important process that lowers the current yield is the thermodynamically favored acid-catalyzed hydrolysis of the peroxodisulfate anion to give peroxomonosulfate, whose anodic reaction leads to increased evolution of oxygen [118]. Therefore, the following requirements for the design have to be considered in order to achieve a high current efficiency:

1) Short residence time in the cell, no backmixing of the anolyte, but high final concentration of the product
2) High anodic current density with minimum heating of the electrolyte
3) Effective dissipation of heat through heat exchangers with large surface areas
4) Small anolyte gap to minimize voltage losses
5) Dimensionally stable anode construction with minimum use of platinum

The first successful industrial realization was the Degussa–Weißenstein cell [119]. A further development is a bipolar electrolyzer [120 – 122] with ion-exchange membranes [123], which is reviewed in [124, 125]. A bipolar electrode plate (see Fig. 7) is the basic element in the filter-press electrolysis cell, which consists of 26 electrodes [124, 126]. The characteristic

feature is the large number of vertical, parallel anolyte channels (9 × 3 mm). The anodes are ribbonlike platinum foils on a carrier, which is cooled from behind. Anolyte and catholyte are separated by a microporous polymer diaphragm or, in a more recent development, by a cation-exchange membrane [127].

The electrolytic conditions for the production of crystalline peroxodisulfate salts are determined by the solubilities of the starting materials and products in the electrolytes, and these in turn are dependent on the proton activity. Fundamental investigations are reported in [128 – 138].

The current efficiency increases in the series $H^+ = Li^+ < Na^+ < NH_4^+$ $K^+ < Rb^+ < Cs^+$ due to the electrostatic effects of the cations in the electrolytic double layer at the electrode/electrolyte phase boundary [139]. The most favorable conditions with respect to solubility ratios and cationic effects are those associated with the production of ammonium peroxodisulfate. Therefore, the ammonium salt is still the most important peroxodisulfate produced electrolytically.

Figure 8 shows a flow diagram for the manufacture of ammonium and sodium peroxodisulfates. During electrolysis ammonium ions and water of hydration enrich the catholyte by migration through the diaphragm. The resulting catholyte excess is mixed with the anolyte to replace the consumed sulfate. After crystallization and separation of ammonium peroxodisulfate, the residual solution is neutralized with ammonia.

Typical operational data for the production of ammonium peroxodisulfate are as follows:

Current density, A/m^2	0.5–1
Cell voltage, V	4–6
Current efficiency, %	75–90
Specific energy consumption, kW · h/kg	1–2
Electrolyte temperature in anolyte, °C	30–45
Anolyte concentrations, g/L	
Inlet cell	
$(NH_4)_2SO_4$	380–440
$(NH_4)_2S_2O_8$	100–160
H_2SO_4	0–150
$(NH_4)SCN$	0.05–0.40
Exit cell	
$(NH_4)_2S_2O_8$	300–350

The electrolytic process is described in [140]. Details of the conversion of ammonium peroxodisulfate to the sodium [141] and potassium [142] salts are given in [143]. Additionally methods for direct electrochemical synthesis of the sodium and potassium salts have been published [144 – 148]. The advantage of these methods is that special equipment for handling ammonia is not required. However, in the direct electrochemical synthesis of sodium and potassium peroxodisulfates, special conditions for the electrolyte concentration and composition have to be considered to avoid solubility and electrolysis problems [146 – 150].

5.3. Uses

The worldwide production capacity of peroxodisulfates in 2005 was estimated to be 165 000 t. The most important manufacturers are FMC (USA), Degussa (Germany), Rhein-PerChemie (Germany), and Mitsubishi Gas Chemical (Japan). Several smaller manufacturers are located in China, where additional capacities are about to be installed. The two largest market segments for peroxodisulfates are polymer production and metal etching, accounting for 85 % of the total market.

Peroxodisulfates are employed as radical initiators in combination with reducing agents and cocatalysts in emulsion polymerization processes for the manufacture of acrylonitrile–butadiene–styrene copolymers (ABS), high-impact polystyrene (HIPS), and styrene–acrylonitrile (SAN) [151, 152]. Redox systems that are commonly used in combination with peroxodisulfates are described in [153].

In the electronics industry peroxodisulfates are employed for etching printed circuit boards and removal of photoresists [154 – 156].

Peroxodisulfates have long been employed for desizing textile goods. A new application is as a bleaching agent in denim finishing [157 – 160].

A very important market are hair-coloring formulations which contain peroxodisulfates as the active ingredient [161, 162].

Sodium peroxodisulfate-based formulations are marketed as shock-treatment chemicals for swimming pool water [163, 164]. Peroxodisulfates are used in the preparation of adjustable-viscosity starch derivatives [165]. Peroxodisulfates have found also application in wastepaper recycling for the oxidation of wet strength resins [166]. An emerging new application is the purification of contaminated soil [167].

Peroxodisulfates have been described as oxidizing agents for photographic fixing baths [168 – 170].

5.4. Analysis

Peroxodisulfate is determined by oxidimetric titration with access of Fe^{2+} (e.g., iron(II) sulfate solution) and back-titration with potassium permanganate [171]. For mixtures with other sulfur compounds, separation by ion chromatography is used [172].

6. Peroxophosphoric Acids and Their Salts

The peroxophosphoric acids are structurally similar to the peroxosulfuric acids and behave similarly. They are hydrolyzed more rapidly than the peroxosulfuric acids, but the oxidation reactions of their anions are kinetically inhibited.

Peroxomonophosphoric acid [*13598-52-2*], H_3PO_5, is obtained by reacting phosphorus(V) oxide with hydrogen peroxide [173, 174]. The reaction proceeds less vigorously if the P_2O_5 has been heat-treated at 350–700 °C [175] or is suspended in an inert solvent [176]. A product containing 88 wt % H_3PO_5 and 9.6 wt % H_2O_2 is obtained. Peroxophosphoric acid is a colorless, viscous liquid. The three ionization constants are $pK_1 = 1.1$, $pK_2 = 5.5$ and $pK_3 = 12.8$ [177]. The salts can be obtained by

neutralization, e.g., with potassium hydroxide, which produces the relatively stable, crystallizable, but hygroscopic salt KH_2PO_5 [176 – 179].

Peroxodiphosphoric acid [*13825-81-5*], $H_4P_2O_8$, can be prepared by anodic oxidation of phosphoric acid. A mixture of peroxodiphosphoric and peroxoxomonophosphoric acid is obtained by reacting cold phosphoric acid with fluorine.

$$2\,H_3PO_4 + F_2 \rightarrow H_2P_2 + O_8 + 2\,HF$$

Peroxodiphosphoric acid is not produced commercially. Several salts have been reported, but only tetrapotassium peroxophosphate has been produced on a commercial scale.

Peroxodiphosphates Potassium peroxodiphosphate $K_4P_2O_8$ [*15593-49-4*], is prepared by electrolysis of potassium phosphate solutions containing added halide or pseudohalide anions [180]. In the older literature, fluorides are mainly recommended for this, but they cause corrosion problems [181]. Nitrates have been successfully tested as an alternative [182]. The electrolytic technique is analogous to that used in the manufacture of peroxodisulfates (see Section 4.3.2) [183, 184]. Sodium and ammonium peroxodiphosphates are obtained by reacting $K_4P_2O_8$ with the corresponding perchlorates, sometimes in the presence of free perchloric acid [185]. Only the secondary and quaternary peroxodiphosphates are obtainable in a crystalline state, with 6 or 18 molecules of water of crystallization. The hexahydrates can be dehydrated under vacuum at 65 °C. Mixed salts such as $K_2(NH_4)_2P_2O_8$ can be obtained by salting out after partial removal of the potassium ions as $KClO_4$ [186].

Potassium peroxodiphosphate is very soluble in water; a saturated solution of $K_4P_2O_8$ contains 42 wt % at 0 °C, 45 wt % at 25 °C, and 51 wt % at 45 °C. The peroxodiphosphates begin to lose oxygen on heating above 200 °C. The potassium salt is the most stable peroxodiphosphate compound [187 – 189]. In solution, the $P_2O_{84}^-$ ions undergo hydrolysis, which is accelerated in the presence of acids [190]. It is a strong oxidizing agent with an oxidation potential of 2.07 V.

The peroxophosphates have very few uses compared to the other peroxo compounds. They have been described as oxidizing agents in cosmetic hair preparations (bleaching, waving, and coloring agents) [191], as etchants for metal surfaces (e.g., aluminum) [192], and radical initiators in the graft polymerization of acrylic and vinylic monomers. However, today peroxophosphates have no commercial use due to their slower reaction kinetics and higher costs compared to the peroxosulfates.

7. Hydrogen Peroxide Addition Compounds

The hydrogen peroxide addition compounds of industrial importance are sodium carbonate peroxohydrate (sodium percarbonate) and urea peroxide (trade name: Percarbamid).

7.1. Sodium Carbonate Peroxohydrate

7.1.1. Properties

Sodium carbonate peroxohydrate [*15630-89-4*], sodium percarbonate, $Na_2CO_3 \cdot 1.5\,H_2O_2$, M_r 157.0, ϱ 2.14 g/cm^3, is a white salt with an orthorhombic unit cell [193]. Commercial crystallized sodium percarbonate consists of coarse, compact grains with a regular spherolitic crystal form [194]. The bulk density can range from 800 to 1200 g/L, depending on the synthesis conditions. The solubility in 100 mL water is 13.1 g at 10 °C, 15.4 g at 20 °C and 18.0 g at 30 °C [195]. The solubility of sodium percarbonate is reduced in the presence of other salts such as Na_2CO_3, Na_2SO_4, and NaCl.

The active oxygen content of technical sodium percarbonate varies between 12.0 wt % and 14.5 wt % (theoretical: 15.28 wt %), depending on the manufacturing process and stabilizing technology.

In contrast to sodium perborate, sodium carbonate peroxohydrate is an addition compound of hydrogen peroxide and sodium carbonate in which the hydrogen peroxide molecule is only weakly bound to the carbonate ion via hydrogen bonding, similar to water of crystallization. Thus, hydrogen peroxide is much more likely to be liberated from sodium carbonate peroxohydrate, for example, in the presence of moisture.

Figure 9. Computer model of crystalline sodium carbonate peroxohydrate

Figure 9 shows a computer model of crystalline sodium carbonate peroxohydrate.

When stored under cool, dry conditions, the rate of active oxygen loss is less than 0.3 % (relative) per month [195]. However, even in the presence of stabilizers, it is much more sensitive to higher temperatures and moisture than sodium perborate. Uncoated sodium percarbonate loses 82–86 % of the active oxygen within 10 d at a relative humidity of 96 % and a temperature of 30 °C [196], whereas sodium perborates loses < 2 %.

The stability of sodium carbonate peroxohydrate is mainly dependent on the presence of water. With increasing humidity the stability decreases as a result of accelerated exchange of the bonded hydrogen peroxide versus water. At the same time, exothermic decomposition of the liberated hydrogen peroxide in the sodium carbonate peroxohydrate, triggered by the caustic environment, yields molecular oxygen and water. Due to the weak bonding of hydrogen peroxide in the crystal lattice of sodium carbonate peroxohydrate, the process of lattice exchange is highly temperature dependent and thus can result in an autocatalytic decomposition reaction, especially if the material is not stabilized properly.

On dissolution of sodium carbonate peroxohydrate in water, the aqueous solution behaves like an alkaline solution of hydrogen peroxide.

Reliable methods for the determination of the decomposition properties of different sodium carbonate peroxohydrate qualities are highly sensitive microcalorimetric measurement methods such as thermal activity monitoring (TAM). Under isothermal conditions, the heat of reaction of the decomposition is measured at a defined temperature as a function of time [197]. The specific thermal output, normally measured in μW/g, is specified at less than 10 to ensure safe storage and handling.

The active oxygen content can be determined by titration with potassium permanganate solution in dilute sulfuric acid or by titration with cerium(IV) sulfate solution. The sodium content is obtained by titration with hydrochloric acid with methyl orange as indicator.

7.1.2. Production

Sodium percarbonate was first prepared by Tanatar in 1899 from hydrogen peroxide and soda ash. The product was isolated by precipitation with ethanol. It was not correctly identified as a hydrogen peroxide addition compound until 1909, when Riesenfeld and Reinold elucidated its structure [198]. Three major processes are used for the industrial manufacture of sodium percarbonate, yielding products with different properties with regard to bulk density, active oxygen content, and stability.

Crystallization Processes. In these processes the production of sodium percarbonate is mainly carried out by crystallization from aqueous solution in continuous or discontinuous manner. A concentrated and filtered solution of sodium carbonate is mixed with a concentrated aqueous solution of hydrogen peroxide, generally stabilized with magnesium salts or alkali metal silicates, in a crystallizer at 10–20 °C. The crystallizer has a clarification zone situated above a stirred zone across which an ascending current of supersaturated sodium carbonate peroxohydrate solution flows. Precipitating particles [199] move countercurrently as a result of gravity and are eluted into a classifier located directly below the crystallizer. The accumulated material at the bottom of the classifier is then removed with a rake. To improve the efficacy of the process salting-out agents like sodium chloride and crystallization aids such as polyphosphates or polyacrylates are used [194, 200 – 203].

The product is obtained as coarse, mechanically stable crystals (Fig. 10), which are cen-

trifuged followed by drying, preferably in a fluidized-bed dryer with an air inlet temperature of 75 – 130 °C. The mother liquor from the centrifuge can be further concentrated [204] and mixed with industrial-grade sodium carbonate (sometimes after adding a magnesium salt), filtered to remove iron compounds, and fed back into the crystallizer [205].

Processes which do not include a salting-out process with sodium chloride [204, 205] are usually less economic because of the lower space–time yield. Solvay describes a process without a salting-out agent, which yields a coarse sodium percarbonate product with enhanced thermal stability over products produced employing sodium chloride as salting-out agent [206].

Figure 10. SEM pictures of sodium carbonate peroxohydrate
Top: Sodium carbonate peroxohydrate produced by a crystallization process with radial beamlike crystal growth lines
Bottom: sodium carbonate peroxohydrate produced by a spray-granulation process with onionlike growth structure

Spraying Processes. Several spraying processes for sodium percarbonate are described in the patent literature. These processes avoid the need for filtration and centrifugation of the crystalline product, and hence less waste is produced during production. In an early process described by Laporte, an aqueous solution or suspension of sodium carbonate and hydrogen peroxide is completely evaporated in a spray dryer [207, 208]. The product has a very low bulk density (ca. 0.35 kg/L) [208]. In further variations and optimizations of this process, described by Solvay, solutions of Na_2CO_3 and H_2O_2 are continuously sprayed separately onto a bed of sodium percarbonate fluidized with hot air [209]. Interox describes an improved continuous spray granulation process with higher hydrogen peroxide yields by using a single nozzle for both solutions. To ensure a long lifetime of the nozzle the addition of crystallization inhibitors like sodium hexametaphosphate to the feed solutions is critical [210].

In another process variation, Degussa describes a continuous spray-granulation process in a fluidized-bed reactor using a three-way nozzle. According to a patent [211], the previously necessary use of phosphorous-containing crystallization inhibitors to prevent blockages and incrustations in and on the nozzle can be avoided if the solutions are sprayed through a single three-substance pulverization nozzle with external mixing of the solutions. A highly attrition resistant product with an active oxygen content of $> 14\,\%$ is obtained [211]. Sodium carbonate peroxohydrate produced by a spray-granulation process is shown in Figure 10.

Dry Methods. In these processes, anhydrous or hydrated sodium carbonate (75–90 wt % Na_2CO_3) is treated with a concentrated solution (50–80 wt %) of hydrogen peroxide, so that only a small amount of water must be removed. This can be achieved in a mixer [212, 213] or in a fluidized-bed reactor [214], in which gaseous hydrogen peroxide can be used [215]. Apart from the long reaction time, these dry processes have the disadvantage that no purification of the sodium carbonate takes place, and therefore these sodium percarbonate products have only moderate storage properties. However, this problem can be solved by recrystalliz-

ing the sodium carbonate before use and by using sodium carbonate monohydrate [214]. FMC describes the use of phosphonic acids as additional stabilizers in the synthesis of sodium carbonate peroxohydrate, yielding a product with an active oxygen content of 11–14 % and improved stability [216].

7.1.3. Stabilization, Storage, Packaging, and Transportation

Active-oxygen-containing compounds have a pronounced tendency to decompose in an autocatalytic (self-accelerated) exothermic reaction. Sodium carbonate peroxohydrate is no exception and decomposes into molecular oxygen, water, and soda ash. There are two ways to stabilize sodium percarbonate. One is to improve the stability of the product (core or intrinsic stability) during the reaction process. The second is to stabilize the product by a separate protective coating to prevent moisture and other incompatible materials coming into direct contact with the peroxohydrate.

Intrinsic Stabilization. On the one hand, the intrinsic stability of sodium carbonate peroxohydrate is affected by the presence of heavy-metal impurities introduced by the raw materials sodium carbonate and hydrogen peroxide. Thus, precipitating agents such as silicates [217, 218] and/or magnesium salts [219], or complexing agents such as phosphates, and phosphonic acid [216], are commonly used. On the other hand, the intrinsic stability is also affected by the presence of excess water, mainly bound as crystal water in unconverted sodium carbonate hydrate or sodium hydrogencarbonate. Proper drying of the finished granulate can significantly improve the stability and reduce the decomposition tendency of sodium carbonate peroxohydrate [220].

Outer Stabilization. The outer stabilization of sodium carbonate peroxohydrate is necessary to improve the stability of the material in the presence of other detergent components. Especially protection against moisture brought into the detergent formulation by other ingredients is critical, since uncontrolled interaction of water with sodium carbonate peroxohydrate can result in loss of the active component. During production the absence of a coating or an insufficient coating can cause severe autocatalytic decomposition reactions accompanied by a strong temperature increase and volume expansion. A variety of coatings for percarbonate are described in the literature. Most of the coatings consist of inorganic substances such as borates [221, 222], perborax [223], sodium silicate [196, 224], sodium sulfate [225], and magnesium salts [226]. Mitsubishi describes a technology based on a two-layer coating with sodium silicate and a magnesium salt, which forms magnesium silicate on the surface of the granules [227]. Also organic coatings have been reported in the literature. Examples are chelating agents [228], fatty acids [229], and organic polymers [230, 231]. To control the liberation of hydrogen peroxide from sodium carbonate peroxohydrate Degussa developed a coating consisting of two layers: an inner layer of sodium sulfate for stability and an outer layer of waterglass for time-delayed release [232].

The degrees of inner and outer stability of sodium carbonate peroxohydrate can both be checked by measuring the microcalorimetric properties of the materials by TAM. Sodium carbonate peroxohydrate qualities with 40 °C TAM values of less than 10 μW/g after 48 h are considered to be stable during transportation, storage, and production, assuming proper handling of the material.

Sodium percarbonate must be stored under cool, dry conditions. Exothermic decomposition with liberation of oxygen can be accelerated by increased temperature, radiation caused by sunlight or steam piping, moisture, and/or contact with decomposition catalysts, e.g., heavy metals, alkali, or dirt. Adiabatic storage conditions can lead to self-accelerating decomposition. Exothermic decomposition may also occur during the manufacturing of detergents when sodium percarbonate is added to the still-warm base powder or when exothermic reactions, such as the rehydration of phosphates, proceed after the addition of sodium percarbonate.

Bulk storage of sodium percarbonate is more critical than storage of sodium perborates, in particular under hot and humid climatic conditions, due to its higher sensitivity to decomposition and caking.

Sodium percarbonate has been assigned recently to transport classification 5.1, oxidizing substances, by all major producers due to a change in the testing methods for oxidizing substances [59].

Sodium percarbonate is supplied in bulk by rail and truck, in big bags, and in 25 kg polyethylene sacks.

7.1.4. Uses

With the shift from sodium perborate to sodium carbonate peroxohydrate due to the ongoing discussion about the ecotoxicological properties of sodium perborate at the end of the 20th century, the most important areas of applications in terms of volume are nowadays all-purpose detergent powders and tablets. In 2004 it was estimated that the worldwide production capacity for sodium carbonate peroxohydrate was several hundred thousand tonnes. A smaller amount of ca. 10 % of sodium carbonate peroxohydrate is used in the growing market of automatic dishwashing detergents, especially tablets. Sodium carbonate peroxohydrate also experienced a revival as bleach additive, mainly as oxy products for stain removal and boosters for laundry and dishwashing detergents. In a niche application, sodium carbonate peroxohydrate plays an important role in denture cleaners, often in combination with peroxomonosulfates like Caroat.

Major producers are Solvay (UK, Germany, Italy, USA) Degussa (Germany, Italy), OCI (USA, Korea), Mitsubishi (Japan), Kemira (Sweden), FMC (Spain), JSC (Russia), Jinke (China) and Aktivsauerstoff Gesellschaft (Austria).

7.2. Urea Peroxohydrate

7.2.1. Properties

Urea peroxohydrate [*124-43-6*], $(NH_2)_2CO \cdot H_2O_2$, M_r 94.1, is a white, crystalline substance that melts with decomposition between 80 and 90 °C. At 20 °C, 100 cm^3 water dissolves 80 g urea peroxohydrate. The pH of aqueous percarbamid solution is 3.5–4.0. Urea peroxohydrate also exhibits good solubility in organic solvents, such as methanol (260 g/L), ethanol (120 g/L), glycerol (440 g/L), and various glycols. The bulk density is ca. 600 g/L.

The hydrogen peroxide content of the commercial products as powder is min. 35.0 wt %, and 33.4 wt % as tablets. The active oxygen content of these products is 16.5 and 15.7 wt %, respectively. When stored under cool and dry conditions, the active oxygen loss is less than 5 % per year. However, it decomposes on heating to form H_2O_2, NH_3, and CO_2. The H_2O_2 is released first with vigorous decomposition, especially in the presence of water [233].

7.2.2. Production

Urea peroxohydrate was first synthesized by Tanatar in 1908 by mixing 30 % H_2O_2 with an aqueous solution of urea. After concentrating the reaction mixture, the product was precipitated by cooling and separated by filtration.

The modern industrial process is based on the same principal. Powdered urea is dissolved in 35 % H_2O_2 in the presence of stabilizers, and the product is crystallized by cooling and concentration [234]. The precipitated solid material is separated from the mother liquor and dried at 30–40 °C. The mother liquor is further concentrated under vacuum and recycled. Alternatively, hydrogen peroxide can be sprayed onto urea in a fluidized bed. Excess moisture is removed by drying under vacuum at 30–40 °C [235].

7.2.3. Stabilization and Packaging

Urea peroxohydrate tends to decompose at elevated temperatures. The shelf life of the product can be improved by adding stabilizers such as NaH_2PO_4 or $Na_2H_2P_2O_7$ [236].

The product is supplied commercially in 25 kg packages as powder or tablets. Suitable packaging materials are polyethylene bags or polyethylene-lined containers.

7.2.4. Uses

Urea peroxide is mainly used in the cosmetics and pharmaceutical industry as a disinfecting and bleaching agent. Percarbamide has been employed as the active ingredient in tooth whiteners

and dentifrice formulations [237 – 240] which are sold in the United States as over-the-counter drugs. Worldwide consumption amounts to several hundred tonnes. The major producer of urea peroxide is Degussa (Germany).

8. Toxicology and Ecotoxicology

Metal peroxides, hydroperoxides, and ozonides cannot reasonably be tested for their toxicological and ecotoxicological properties due to their high reactivity to water with formation of oxygen and metal hydroxide or reaction with carbon dioxide to give metal carbonates. The toxicity is mediated by the high corrosivity to skin and mucous membranes of concentrated hydroxide solutions. Additionally, after direct contact with metal peroxides thermal burns can be developed due to the highly exothermic reaction with water.

8.1. Toxicology

Most inorganic peroxo compounds are expected to have a similar toxicity profile to hydrogen peroxide as they release hydrogen peroxide on contact with water, with the exception of the peroxodisulfates.

Available acute toxicity data of the peroxo compounds are summarized in Table 2. All substances tested are of low toxicity by the dermal route and of low to moderate toxicity after oral administration or inhalation exposure. The effects observed are characterized by irritation and inflammation of the skin and mucous membranes at the site of application.

The results of skin and eye irritation and skin sensitization studies are summarized in Table 3. Most of the compounds, except potassium peroxomonosulfate triple salt, which is corrosive, are nonirritating or only slightly irritating to skin, whereas eye irritation was evident for most of the substances. Some compounds cause irreversible corneal damage to the eye. Skin sensitization has only been reported for the peroxodisulfates. In humans, irritative and contact dermatitis but also asthmalike symptoms after exposure to higher airborne concentrations (> 1 mg/m^3) have been reported with peroxodisulfates [269, 270]. These effects are possibly

Table 2. Acute toxicity data for peroxo compounds

Substance	LD_{50} (rat, oral), mg/kg	LD_{50} (dermal), mg/kg	LC_{50} (rat, inhalation), mg/m^3

Table 3. Experimental findings on irritation and skin sensitization by peroxo compounds

Substance	Skin irritation (rabbit)	Eye irritation (rabbit)	Skin sensitization (guinea pig)
Ammonium peroxodisulfate	not irritating [256]	slightly irritating [257]	sensitizing (optimization test) [258]
Sodium peroxodisulfate	not irritating [259]	not irritating [242]	sensitizing (optimization test) [260], not sensitizing (Buehler Test) [242]
Potassium peroxodisulfate	not irritating [242]	not irritating [242]	
Potassium bis(peroxomonosulfate) bis sulfate (Caroat)	corrosive [261]	highly irritating/corrosive [262]	not sensitizing (maximization test) [263]
Sodium percarbonate	slightly irritating [264]	highly irritating/corrosive [265]	not sensitizing (Bühler Test) [266]
Sodium perborate monohydrate	slightly irritating [254]	highly irritating/corrosive [254]	not sensitizing (Bühler Test) [268]
Sodium perborate tetrahydrate	not irritating [267]	irritating [267]	

related to a direct histamine-liberating activity of peroxodisulfates. Sensory irritation studies in mice with sodium peroxodisulfate and sodium percarbonate resulted in RD_{50} concentrations (concentrations that resulted in a 50 % depression of the respiratory rate) of 2250 mg/m^3 [242] and 700 mg/m^3 [271], respectively.

After repeated exposure to inorganic peroxo compounds, toxic effects are normally limited to irritative and inflammatory changes at the site of contact. After repeated inhalation exposure of rats with ammonium peroxodisulfate aerosol (1–20 mg/m^3, 23.5 h/d, 7 d) effects indicative of irritation and inflammation of the respiratory tract including the lung were observed; the no observed adverse effect level (NOAEL) was 1 mg/m^3 [272]. A 90-d inhalation study in rats exposed 6 h per day for 5 d per week to concentrations of 5, 10, or 25 mg/m^3 of ammonium peroxodisulfate revealed an NOAEL of 10 mg/m^3, with the only effects being local irritation of trachea, bronchi/bronchioles, and lungs. In this study a NOEL of 5 mg/m^3 was identified based on sporadic rale and effects on the respiratory rate in the 10 mg/m^3 dose group. All effects were reversible during a 6-week recovery period. No systemic effects or histopathological changes in any organs distant from the site of first contact were observed [242]. Rats exposed to concentrations of 1.4–43 mg/m^3 of potassium bis(peroxomonosulfate) bis-sulfate dust by inhalation for 6 h/d, 5 d per week for 2 weeks showed severe ocular irritation as the main effect (NOAEL 1.4 mg/m^3); no pathological changes in other organs were observed [275].

No effects were observed in male rats receiving up to 1000 ppm sodium peroxodisulfate or potassium peroxodisulfate in the diet (corresponding to 137 mg/kg bw or 131.5 mg/kg bw, respectively) for 28 d [242]. In a 28-d feeding study in male rats with ammonium peroxodisulfate an NOAEL of 300 ppm in the diet, corresponding to 41 mg/kg bw was identified based on a decreased adrenal weight to body weight ratio at 82 mg/kg bw [242]. In a 13-week feeding study in rats with 3000 ppm sodium peroxodisulfate in the diet (corresponding to 300 mg/kg bw) local effects on the mucous membranes of the gastrointestinal tract were found, but no systemic toxicity was observed. The NOAEL in this study was 300 ppm or 30 mg/kg bw [269, 270]. In a 28-d study in rats receiving 1000 mg/kg bw of sodium perborate tetrahydrate by gavage, similarly the observed effects could be releated to irritation of the mucous membranes in the gastrointestinal tract [276].

The effects observed are consistent with the liberation of hydrogen peroxide by the peroxo compounds, which showed similar effects after repeated oral administration. In a 90-d drinking water study in mice receiving 100 to 3000 ppm of hydrogen peroxide, irritation of the mucous membranes of the gastrointestinal tract was observed (the NOAEL was 100 ppm, corresponding to 26 or 37 mg/kg/day for male and female mice, respectively). No systemic effects were observed [274]. Hydrogen peroxide is rapidly degraded in the exposed tissues and blood, catalyzed by metabolic enzymes such as catalases or peroxidases. Therefore systemic availability of peroxo compounds and hydrogen peroxide is thought to be low [273].

Ammonium and sodium peroxodisulfates were nonmutagenic in a variety of in vitro and in vivo test systems for point mutations and chromosomal aberrations with and without a metabolic activation system [242, 269, 277 – 280] and potassium bis(peroxomonosulfate) bis-sulfate was nonmutagenic in the Ames assay [281].

Results of mutagenicity studies with sodium perborate were comparable to those with hydrogen peroxide [273, 282 – 285].

While in vitro assays for gene mutation and chromosomal aberration were positive in the absence of a metabolic system (rat liver supernatant, catalase), the mutagenic activity was reduced or abolished when an exogenic metabolic system was added [273, 282, 283]. No in vivo data for sodium perborate are available, but hydrogen peroxide was nonmutagenic with regard to chromosomal aberrations or micronuclei in rats and mice as well as in a study for unscheduled DNA synthesis in rats [273, 284].

No carcinogenicity studies are available for peroxo compounds, but the carcinogenic effects of hydrogen peroxide were studied in rats and different strains of mice after oral administration. [272 – 288]. Available evidence suggests that hydrogen peroxide and peroxo compounds are not likely to cause cancer in humans except by uncommon or unlikely routes of exposure [289].

Table 4. Ecotoxicity data of peroxo compounds

Substance	Acute toxicity for fish LC_{50}, 96-h (mg/L)	Acute toxicity for daphnia EC_{50}, 48-h (mg/L)	Chronic toxicity for algae EC_{50}, 72-h (mg/L)
Ammonium peroxodisulfate	*Oncorhynchus mykiss* 76.3 [295]	*Daphnia magna* 120 [298]	*Scenedesmus quadricauda* 33 [a] (growth rate) [300] *Selenastrum capricornutum* (growth rate): 83.7 [242]
Sodium peroxodisulfate	*Oncorhynchus mykiss* 163 [242]	*Daphnia magna* 133 [299]	*Selenastrum capricornutum* (biomass): 116 [242]
Potassium peroxomonosulfate triple salt	*Brachydanio rerio* $> 32 < 56$ [301]	*Daphnia magna* 5.3 [b] [303]	
Sodium percarbonate	*Pimephales promelas* 71 [302]	*Daphnia pulex* 4.9 [304]	*Anabaena spec* (blue-green) 8 [c] [305] *Chlamydomonas spec* (green) 60 [d] [305]
Sodium perborate monohydrate	*Brachydanio rerio* 51 [306]	*Daphnia magna* 11 [307]	*Selenastrum capricornutum* 3.3 (biomass) [308] 6.3 (growth rate) [308]

[a] EC_{10} (96-h).
[b] 24-h.
[c] 140-h.
[d] 240-h.

No effects on male and female fertility were observed in a one-generation study in rats with ammonium peroxodisulfate up to the highest tested dose level of 250 mg (kg bw)$^{-1}$d^{-1} in the diet. No effects on embryo/fetal viability up to day 4 of lactation were observed in the same study. The NOAEL for both fertility and developmental toxicity was 250 mg (kg bw)$^{-1}$d^{-1} [242].

A potential for systemic toxicity of sodium perborates could be the formation of boric acid. However the uptake of boric acid in the body is limited by the simultaneous liberation of hydrogen peroxide that reduces local blood circulation. After repeated oral administration of high doses of boric acid to experimental animals, effects on male fertility (testicular atrophy) and developmental toxicity were observed [290]. For sodium perborate there is no indication of any effect on reproductive organs in a repeated dose study by the oral route (28 d, 7 d per week at 1000 mg (kg bw)$^{-1}$d^{-1}) in rats at dose levels corresponding to boron doses that already revealed considerable testicular toxicity in studies with boric acid. As these perborate doses corresponded to the maximum tolerated dose in the animals, it can be concluded that sodium perborate did not cause any testicular effect in rats at the maximum tolerated dose of 1000 mg (kg bw)$^{-1}$d^{-1} [254]. In a developmental toxicity study by the oral route in rats with sodium perborate tetrahydrate, fetotoxic effects were only observed at dose levels that were already maternally toxic [254].

No occupational exposure limits exist for perborates, sodium percarbonate, and peroxomonosulfate. Occupational exposure limits have been established for hydrogen peroxide in different countries, for example, by ACGIH [288], the Dutch Social Economic Council [290], the UK Health and Safety Executive (HSE) [291], Belgium [292], the French Ministry of Labour [293], and the German AGS (Auschuss für Gefahrstoffe) [294]: 8-h TWA: 1.4 mg/m^3 or 1.5 mg/m^3. A 15-min STEL of 2.8 mg/m^3 was established by HSE (max. 1 h in a 24 h period) [291], and a 15-min. STEL of 1.4 mg/m^3 by AGS [294].

For peroxodisulfates occupational exposure limits have been established by ACGIH (8-h TWA: 0.1 mg/m^3 [288]), the UK HSE, and Belgium (8-h TWA: 1 mg/m^3 [291, 292]).

8.2. Ecotoxicology

Ecotoxicological data are available for a number of peroxo compounds. The data are summarized in Table 4.

Peroxodisulfates are of low to moderate toxicity to aquatic organisms in standard tests [295 – 300].

Potassium peroxomonosulfate triple salt and sodium percarbonate exhibit moderate toxicity to fish, daphnia, and algae [301 – 305].

Sodium perborate monohydrate is of moderate toxicity to fish, daphnia, and algae [306 – 308]. Algae seem to be the most sensitive phylum.

Peroxo compounds tend to decompose in natural waters to give hydrogen peroxide and ultimately oxygen and water. In wastewater peroxide was shown to decompose before reaching the sewage treatment plant [309]. Therefore it is expected that peroxo compounds do not persist long enough in water to cause an impact on the environment in low concentrations. Given the polarity and high water solubility of peroxo compounds, a potential for bioaccumulation is not anticipated.

1. Introduction

Peroxides are characterized by the presence of the peroxo group −O−O−. In organic peroxides this group is bound to at least one carbon atom, or is bound to a carbon atom via another atom [1–14].

The first synthesis of an organic peroxide was that of dibenzoyl peroxide in 1858 [15]. Since then, a large number of organic peroxides have been synthesized, mainly on a laboratory scale. Interest in organic peroxides arose mainly in connection with biological processes [16] and the aging of organic compounds such as rubber, fats [17], oils, paints, and solvents, in which peroxides are often formed as reactive intermediates. Since the mid-1970s a surprisingly large number, with regard to the relative instability of the peroxo group, of naturally occurring peroxo compounds have been isolated and characterized.

Figure 1. Consumption trend for organic peroxides in the United States

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a19_199

Industrial interest in organic peroxides began in the early 1900s with the introduction of benzoyl peroxide as a bleaching agent. The consumption of synthetic plastics has increased since the 1940s, resulting in the increasing importance of peroxides as initiators for the radical polymerization of vinyl monomers. Additional applications include their use as cross-linking agents for polyolefins, as hardeners for elastomers, as adhesion promoters for metal – plastic composites (e.g., polyethylene coatings), and in pharmaceuticals. Various organic peroxides have become industrially important as selective oxidation and epoxidation reagents (→ Epoxides). Peroxides are frequently generated in situ because of handling problems.

More than 65 organic peroxides in more than 100 formulations (liquid, solid, paste, powder, solutions, dispersions) are produced in industrial quantities today. An overview of the consumption of organic peroxides in the United States is given in Figures 1 [18] and Fig. 2.

Formally, organic peroxides can be regarded as derivatives of hydrogen peroxide in which the hydrogen atoms are substituted by various organic groups. The following classes can be distinguished:

Alkyl hydroperoxides	$R-O-O-H$
Dialkyl peroxides	$R^1-O-O-R^2$
Peroxycarboxylic acids	$R-\overset{O}{\overset{\|\|}{C}}-O-O-H$
Diacyl peroxides	$R^1-\overset{O}{\overset{\|\|}{C}}-O-O-\overset{O}{\overset{\|\|}{C}}-R^2$
	$R^1-\overset{O}{\overset{\|\|}{C}}-O-O-SO_2-R^2$
Peroxycarboxylic esters	$R^1-\overset{O}{\overset{\|\|}{C}}-O-O-R^2$
Peroxycarbonates	$R^1-O-\overset{O}{\overset{\|\|}{C}}-O-O-R^2$
α-Oxy-, α-amino peroxides	$R^1-\underset{X}{\overset{R^2}{C}}-O-O-R^3(H)$

$X = -OH,\ -OR^4,\ -O-O-,\ -NH_2,\ -NHR^5,\ -NR^5R^6$

Compounds in which the peroxy group is bonded to one or two atoms other than carbon are also regarded as organic peroxides, as long as additional organic substituents are present. Peroxides with the general structures

$$-\overset{|}{\underset{|}{C}}-O-O-M \quad \text{and} \quad -\overset{|}{\underset{|}{C}}-M-O-O-M-\overset{|}{\underset{|}{C}}-$$

where M is an element of groups 1, 2, 4, 5, 6, 8 or 12 – 16 of the periodic table have been synthesized in large numbers [19]. Furthermore, representatives of other substance classes, in which the peroxy group is connected to a heteroatom, are known. With few exceptions, compounds of this type are only of academic interest.

Figure 2. Consumption of organic peroxides (in tonnes) in the United States in 1983
MEK peroxide = methyl ethyl ketone peroxide

Homolytic cleavage of the O – O bond, readily induced by light or heat, is a typical reaction of organic peroxides. The reactivity depends strongly on the structure of the organic peroxy compound. In addition, heterolytic and hydrolytic cleavage, and rearrangements are also known. The oxidation potential decreases in the following order: peroxycarboxylic acids > hydroperoxides > diacyl peroxides > peroxycarboxylic esters > dialkyl peroxides.

Within a given class of compounds the stability increases with increasing carbon content. The thermal stability is often characterized by the half-life or the 10-h half-life temperature, whereby the radical initially formed upon decomposition is very short-lived, i.e., $t_{1/2} < 10^{-3}$ s [20]. Typical 10-h half-life temperatures of commercial peroxides lie between 25 and 170 °C. Decomposition is accelerated by various transition metals (promoters).

There are two main methods for the production of organic peroxides: (1) from hydrogen

peroxide and its derivatives and (2) by oxidation with oxygen.

Analytical methods for peroxides include the usual spectroscopic [21] and chromatographic procedures [22], as well as various methods based on oxidative titrations (iodometry) [23] and electrochemical techniques [24]. Particular attention must be paid to safety factors when dealing with peroxides. Many peroxy compounds are not only heat sensitive, but are also sensitive to shock, impact, and light. Peroxides tend to decompose explosively. These compounds are frequently handled in desensitized form.

2. Alkyl Hydroperoxides

The formal substitution of a hydrogen atom in hydrogen peroxide by an alkyl group gives a hydroperoxide with the general formula R–OOH. Primary, secondary, and tertiary hydroperoxides are known; vinyl hydroperoxides have not yet been synthesized.

Hydroperoxides occur widespread in nature. They occur mainly as intermediates during decomposition, and by aging of organic compounds under the influence of atmospheric oxygen (autoxidation):

These compounds are oxidized further to frequently strong-smelling aldehydes, ketones, and carboxylic acids; an example is the smell of rancid fat [25]. Autoxidation is used industrially in the drying of paints (→ Drying Oils and Related Products).

2.1. Properties

Physical Properties. Hydroperoxides are generally sufficiently stable to be melted or distilled at a temperature below 80 °C. Decomposition increases markedly with increasing temperature; under certain circumstances explosions may occur. The thermal stability is mainly determined by the dissociation energy of the O–O bond; for homolytic cleavage a typical value is 180–184 kJ/mol [26], [27]. A summary of the physical properties of some important hydroperoxides is shown in Table 1.

The acidity of hydroperoxides is greater than that of the corresponding alcohols, so that in most cases salts can be prepared. This property is often exploited for isolation and purification [28], [29]. The acid strengths (pK_a at 20 °C) of some hydroperoxides are as follows [30]:

Methyl hydroperoxide	11.5
Ethyl hydroperoxide	11.8
Isopropyl hydroperoxide	12.1
Cumene hydroperoxide	12.6
tert-Butyl hydroperoxide	12.8
Triphenylmethyl hydroperoxide	13.07

When dissolved in noncoordinating solvents hydroperoxides form mainly dimers and trimers with six-membered ring structures.

Chemical Properties. Alkyl hydroperoxides can react with retention or cleavage of the O–O bond. In the first instance, substitution of the hydrogen atom on the peroxy oxygen atom leads to a whole series of products:

Reactions in which the O–O bond is cleaved are important for the quantitative analysis of hydroperoxides (e.g., by iodometry). Under basic conditions some hydroperoxides decompose to give carbonyl compounds, for example:

Tertiary hydroperoxides decompose under basic conditions to form the corresponding alcohol and oxygen:

Under acidic conditions hydroperoxides decompose with rearrangement; a classic example

Table 1. Physical properties of some alkyl hydroperoxides-4

[c] At 23 °C.

is the industrial synthesis of acetone and phenol from cumene hydroperoxide by the Hock process (→ Acetone , Chap. 4.1.). In the presence of a polymer with acidic groups, hydrogen peroxide and isobutene can be obtained from *tert*-butyl hydroperoxide [31]. The thermal decomposition of primary alkyl hydroperoxides takes place with homolytic cleavage, whereas for secondary and tertiary hydroperoxides homolytic cleavage can be observed for both thermal and photolytic decomposition [32]. The radicals formed in these processes are reactive species that can react, for example, with compounds containing C = C double bonds, either by addition or by substitution of a hydrogen atom. Peroxy radicals react with alkyl groups in the presence of metal ions (M) to give dialkyl peroxides and the corresponding alcohol in yields of up to 90 %:

$$2R-OOH + R'-H \xrightarrow{M^+} R-OOR' + R-OH + H_2O$$

In the absence of a suitable substrate, symmetrical dialkyl peroxides are formed with elimination of oxygen:

$$3R-OOH \xrightarrow{M^+} R-OH + R-OO-R + H_2O + O_2$$

2.2. Production

Several methods are known for the production of alkyl hydroperoxides. Essentially three major production routes exist, which can be differentiated according to the origin of the peroxy group:

1) From hydrogen peroxide
2) From oxygen (atmospheric oxygen, singlet or triplet O_2)
3) From another peroxy compound

Only a few processes can be carried out on a large scale and are of industrial importance.

Alkylation of Hydrogen Peroxide. Hydrogen peroxide can be alkylated under acidic or basic conditions by alkyl halides, alkyl sulfonates [33], carboxylic and sulfonic acid esters, ethers, tosylhydrazine, and cyclopropanes [34–36]. Dialkyl peroxides, which are often difficult to remove, are formed in addition to the monoalkylation product. A further limitation of this method is the safety measures required, as the lower molecular mass hydroperoxides in particular tend to undergo explosive decomposition. In another method, primary, secondary, and tertiary hydroperoxides are formed by reaction of an alkyl halide with hydrogen peroxide in the presence of silver trifluoroacetate [37]. The relatively stable tertiary hydroperoxides [38] (e.g., *tert*-butyl hydroperoxide) are of particular industrial importance.

$$(CH_3)_3C-OH \xrightarrow{H_2O_2/H_2SO_4} (CH_3)_3C-OOH$$

The remarkably stable acetylene mono- and dihydroperoxides can also be prepared in this way. These compounds have found some industrial interest as starting materials for the correspond-

ing dialkyl peroxides, which are used as high-temperature polymerization initiators [39]:

Primary and secondary hydroperoxides can only be obtained in moderate yields from hydrogen peroxide and an alkylating agent [40].

Halogen-substituted hydroperoxides can be obtained in good yields by the reaction of electron-rich olefins with hydrogen peroxide and a halogen [41]:

Halogen-substituted hydroperoxides can also be formed by peroxymercuration with subsequent substitution of the acetoxymercury(II) group with halogens [42].

Oxidation with Oxygen. The insertion of oxygen into an alkane C – H bond leads initially to hydroperoxides. When this reaction is carried out with atmospheric oxygen it is known as autoxidation. It frequently leads to a multitude of products because of further spontaneous reactions. Therefore, this reaction is of limited synthetic use. Moreover, these reactions are generally very slow and require high temperature (usually > 100 °C).

The process involves a radical mechanism, which can be started by radical initiators (peroxides [43], azo compounds [44], halogens, or hydrogen halides [45]), photochemically, thermally [46], and by various transition metal ions.

Initiation:	$RH \longrightarrow R\cdot + H\cdot$
Chain propagation:	$R\cdot + O_2 \longrightarrow ROO\cdot$
	$ROO\cdot + RH \longrightarrow ROOH + R\cdot$
Chain termination:	$2\,R\cdot \longrightarrow R-R$
	$ROO\cdot + R\cdot \longrightarrow ROOR$
	$2\,ROO\cdot \longrightarrow O_2 + ROOR$

Tertiary carbon atoms are preferentially attacked because of the lower dissociation energy of the C – H bond compared with those of primary and secondary centers. Selective preparation of hydroperoxides can be achieved mainly by reaction of activated hydrogen atoms (benzylic hydrogen atoms, hydrogen atoms in the α-position to carbonyl groups). This method is of industrial importance for the production of cumene hydroperoxide, *tert*-butyl hydroperoxide, 1,4-diisopropylbenzene hydroperoxide, pinane hydroperoxide, and phenethyl hydroperoxide. In contrast to the oxidation of saturated hydrocarbons, autoxidation takes place even at room temperature.

tert-Butyl Hydroperoxide [*75-91-2*]. The oxidation of isobutane with oxygen in the gas phase at 160 °C and a residence time of ca. 3 min leads to a 70 % yield of *tert*-butyl hydroperoxide with a conversion of 80 %. Hydrogen bromide is used as the initiator [47]. Byproducts include di-*tert*-butyl peroxide, *tert*-butanol, and various alkyl bromides. Another process operates in the liquid phase at 130 °C and 3.5 MPa without a catalyst. The hydroperoxide is obtained in a yield of ca. 60 % with an isobutane conversion of < 25 % [48].

Cumene Hydroperoxide [*80-15-9*]. Cumene is oxidized with atmospheric oxygen at 120 °C. The selectivity is 95 % at a conversion of 15 % [49–53].

A method for the preparation of hydroperoxides that are not easily accessible by other routes is the reaction of organometallic compounds (Grignard reagents, zinc and cadmium compounds) with oxygen at 0 °C. This method leads to tertiary hydroperoxides in good yields, and primary and secondary hydroperoxides in moderate yields [54].

This method is particularly suitable for the production of low molecular mass hydroperoxides. Alternative synthetic routes via boranes [55] and ozonides are also known.

Peroxygenation of alkenes with triplet oxygen proceeds via the intermediate allyl radical; numerous allyl hydroperoxides can be formed due to resonance of the allyl radical:

Various alkynes can be converted to propargyl hydroperoxides (2-alkynyl hydroperoxides) by treatment with triplet oxygen.

Alkenes that contain at least one allylic hydrogen atom undergo an allylic shift on reaction with singlet oxygen to give 2-alkenyl hydroperoxides [56–60]:

2.3. Uses

tert-Butyl hydroperoxide is used as an oxidant in the Halcon process for the production of propylene oxide. The standard commercial product (80 %, stabilized with water and phosphoric acid) is suitable for curing polyester resins and for the emulsion polymerization of styrene – butadiene rubbers.

In addition to the synthesis of phenol, cumene hydroperoxide is also used for the polymerization of dienes and for the cross-linking of sulfide rubbers. Furthermore, it is the starting material for dicumyl peroxide. The usual commercial product is an 80 % solution in cumene. Various heterocyclic hydroperoxides are employed as cross-linking agents for olefin polymers [61].

3. Dialkyl Peroxides

Dialkyl peroxides have the general formula R – O – O – R′, where R and R′ represent alkyl-, alkenyl-, or aryl groups. Both symmetrical (R = R′) and mixed (R ≠ R′) peroxides are known as well as numerous cyclic peroxides. Only the relatively stable tertiary dialkyl peroxides have so far gained any industrial importance.

3.1. Properties

Physical Properties. Several dialkyl peroxides can be distilled at atmospheric pressure or under vacuum without decomposition. Their dissociation energy is about 170 – 180 kJ/mol [2], [3]. Primary dialkyl peroxides such as dimethyl peroxide are shock sensitive and explosive. The physical properties of some dialkyl peroxides are listed in Table 2.

Chemical Properties. Dialkyl peroxides can be cleaved homolytically by the action of heat or light to give alkoxy radicals:

The subsequent reactions of these radicals depend on their structure, on the conditions, and on the temperature [62], [63]. In the absence of a substrate the main products result from disproportionation:

The reaction of the intermediate methoxy radical with formaldehyde then leads to methanol and carbon monoxide:

Secondary dialkyl peroxides lead analogously to the corresponding ketones and alcohols. Tertiary dialkyl peroxides undergo rearrangement to form ketones, alcohols, and epoxides, in addition to lower hydrocarbons. The main products of the decomposition of di-*tert*-butyl peroxide are acetone and ethane:

Numerous synthetic reactions are possible in the presence of reactive substrates [64], [65], of which the most important is the production of tertiary alkyl esters [66].

Table 2. Physical properties of some dialkyl peroxides-,4

[a] At 0 °C. [b] At 17 °C. [c] At 25 °C. [d] Supercooled melt at 21 °C.

3.2. Production

Dialkyl peroxides can be obtained from numerous starting materials by reaction with oxygen, hydrogen peroxide, alkyl hydroperoxides, and in some cases potassium peroxide.

Oxidation with Oxygen. For the production of acyclic dialkyl peroxides, the autoxidation of hydrocarbons with molecular oxygen is only suitable in certain cases. This method can only be used when the intermediate radical formed is stabilized, e.g., by alkyl or aryl substituents, or by allylic conjugation. In these reactions, either a C–H bond is cleaved initially [67], (e.g., in the case of 2-methylpropane) or formal insertion of oxygen can take place following cleavage of a C–C or a C–X bond (X = halogen):

$$Ph_3C-CPh_3 \longrightarrow 2\,Ph_3C^{\bullet} \xrightarrow{2O_2} 2\,Ph_3C-O-O^{\bullet}$$
$$Ph_3C-O-O^{\bullet} + Ph_3C^{\bullet} \longrightarrow Ph_3C-O-O-CPh_3$$

$$Ph_3C-O-O^{\bullet} + Ph_3C^{\bullet} \longrightarrow Ph_3C-O-O-CPh_3$$

With various alkenes, such as styrene, acrylates, acrylonitrile, and vinyl chloride, autoxidation leads to polymeric dialkyl peroxides with the general structure:

$$n\,HC(X)=CH_2 \xrightarrow{nO_2} \left[CH_2-CH(X)-O-O\right]_n$$

X = C_6H_5, COOR, CN, halogen

The oxidation of conjugated dienes (photooxygenation [68]) with oxygen leads either to polymers or to cyclo adducts (hetero-Diels–Alder adducts), i.e., the 1,4-epiperoxides, which are rarely accessible by other routes. The autoxidation of α-terpinene to give ascaridole is an example of the synthesis of an epiperoxide [69]:

The photosensitized autoxidation of polynuclear aromatic hydrocarbons has been known for a long time [70].

The [2 + 2] cycloaddition of singlet oxygen to alkenes offers a simple route to 1,2-dioxetanes [71–76], which are of particular interest in connection with chemi- and bioluminescence.

Alkylation of Hydrogen Peroxide. The dialkylation of hydrogen peroxide using alkyl halides, alcohols, alkenes, or alkyl sulfates gives symmetrical dialkyl peroxides and takes place under conditions similar to those described for monoalkylation in Section 2.2.

Dicumyl peroxide [*80-43-3*]. The reaction of an H_2O_2 –urea adduct with 2-phenyl-2-propanol at 35 °C in the presence of a mineral acid catalyst gives dicumyl peroxide in good yields [77].

Di-tert-amyl peroxide [*10508-09-5*] is formed in 68 % yield by slow addition of *tert*-amyl alcohol to a mixture of H_2O_2 and H_2SO_4 at 20 °C [78].

Alkylation of Hydroperoxides. The best method for the production of both symmetrical and unsymmetrical dialkyl peroxides is the alkylation of hydroperoxides with alcohols, olefins, esters, ethers, halides, or epoxides [79].

Dicumyl Peroxide. The reaction of cumene hydroperoxide with 2-phenyl-2-propanol in the presence of a mineral acid catalyst gives dicumyl peroxide in almost quantitative yield [49–53], [80–82].

Di-tert-butyl peroxide [*110-05-4*] is synthesized from *tert*-butyl hydroperoxide and *tert*-butanol [49–53], [80–83]. This reaction can also be carried out with an acidic ion-exchange resin as catalyst, the water produced in the reaction being removed by azeotropic distillation [84].

Bis(tert-amylperoxy)-2,5-dimethylhexane [*78-63-7*] is formed in 79 % yield from 2,5-dihydroperoxy-2,5-dimethylhexane and *tert*-amyl alcohol at 50 °C in the presence of sulfuric acid [85].

Phenols can be converted to dialkyl peroxides (quinone peroxides) by dehydrogenation [86–88]. These compounds have been investigated primarily in connection with the mechanism of action of phenolic antioxidants [89–91].

3.3. Uses

Due to their relatively high thermal stability, dialkyl peroxides are used mainly as catalysts for suspension and bulk polymerization [92], [93]. They also find use as hardeners for unsaturated polyester resins and for the cross-linking of polymers [94]. In addition to di-*tert*-butyl peroxide [95] and dicumyl peroxide, bis(*tert*-alkylperoxy) alkanes are employed. The dialkyl peroxides are commercially available as technical-grade material and as 40 – 50 % solutions.

4. Peroxycarboxylic Acids

Peroxycarboxylic acids have a wide range of applications in preparative and industrial chemistry on account of their high oxidation potential. Due to their instability some peroxycarboxylic acids are either generated in situ or used in desensitized form.

4.1. Properties

Physical Properties. Short-chain aliphatic peroxycarboxylic acids are infinitely miscible with water and possess an unpleasant, pungent odor. They are explosive when pure or highly concentrated. The tendency to explode decreases with increasing chain length. Long-chain peroxycarboxylic acids ($> C_6$) are increasingly water-insoluble solids. Aromatic peroxycarboxylic acids are only slightly soluble in water; both types are, however, soluble in various organic solvents.

In the crystalline state peroxycarboxylic acids associate to form dimers (**2**), whereas in the gas phase, in the molten state, and in solution in noncoordinating solvents monomers (**1**) with intramolecular hydrogen bonds are present [96].

In the presence of donor compounds (Do) such as tetrahydrofuran, 1,4-dioxane, or *N*,*N*-dimethylacetamide, peroxycarboxylic acids form complexes with cleavage of the intramolecular hydrogen bonds [97], [98]:

Peroxycarboxylic acids exhibit pK_a values that are 3 – 4 units lower than those of the corresponding carboxylic acids [99] due to the absence of resonance stabilization in the peroxycarboxylate anions. As a result of the weak substituent effect, the pK_a values all lie in a small range. Table 3 lists physical properties for some peroxycarboxylic acids.

Under certain circumstances peroxycarboxylic acids can decompose explosively on heating or under impact. The dissociation energy of the O – O bond (80 – 90 kJ/mol) is considerably lower than that of the hydroperoxides or the dialkyl peroxides [100–102].

Chemical Properties. Peroxycarboxylic acids have the highest oxidation potential of all organic peroxides, whereby the corresponding carboxylic acid is formed with release of active oxygen. The stability of aqueous solutions of peroxycarboxylic acids depends on the pH. Bases cause decomposition with loss of active

Table 3. Physical properties of some peroxycarboxylic acids-,4

	2:1	22.8 (11.6)	45.2 (29.2)	23.6 (50.9)	7.2 (8.2)	70
	4:1	18.6 (11.1)	62.4 (47.2)	15.3 (38.5)	2.4 (3.2)	76
	6.66:1	13.8 (9.0)	73.3 (60.8)	10.4 (28.8)	9.2 (1.3)	86
	10:1	10.1 (7.0)	81.0 (70.8)	7.4 (21.6)	0.5 (0.7)	90
90	1.5:1	45.0 (27.8)	35.0 (27.4)	14.0 (36.5)	6.0 (8.3)	77

oxygen, whereas in acidic media an equilibrium is established.

$$R-CO_3H + H_2O \overset{H^+}{\rightleftharpoons} R-CO_2H + H_2O_2$$

With the exception of performic acid, neutral solutions are largely hydrolytically stable. Peroxycarboxylic acids decompose thermally by two mechanisms [103]: radical and concerted:

$$R-CO_3H \rightarrow R-OH + CO_2 \quad (1)$$
$$R-CO_3H \rightarrow R-CO_2H + 1/2\,O_2 \quad (2)$$

In the absence of oxygen, the radical decomposition (Eq. 1), in which the first step is homolytic cleavage of the O – O bond, dominates. Heavy metal ions accelerate the radical decomposition even at low temperatures. In contrast, in the presence of radical inhibitors the concerted

reaction (Eq. 2) takes place. It is facilitated by the stereochemistry of the peroxycarboxyl group, which is able to form a five-membered cyclic transition state [103], [104].

In the presence of urea, starch, cholic acid, or zeolites, straight-chain peroxycarboxylic acids form inclusion compounds [105], [106]. Isolable 1 : 1 complexes are obtained with triphenylphosphine oxide, triphenylarsine oxide, and heteroaromatic *N*-oxides [107].

Table 5. Azeotropic mixtures of peroxycarboxylic acids and water-,4

Compound	Peroxycarboxylic acid, wt %	Water, wt %
Peracetic acid	61.0	39.0
Peroxypropanoic acid	51.5	48.5
Peroxybutanoic acid	42.0	58.0
Peroxyisobutanoic acid	55.5	44.5

Qualitative detection of peroxycarboxylic acids is facilitated with reagents that give colored products on oxidation, e.g., alkali-metal iodides, titanium sulfate, or phenolphthalein. For quantitative analysis potentiometry [3], polarography [5], and iodometric titration are suitable. IR and NMR spectroscopy are also useful for determination of peroxycarboxylic acids [108].

4.2. Production

Peroxycarboxylic acids can be produced by numerous methods, some of which are shown in Figure 3. Of these methods, however, only the first five are synthetically and industrially important. Production from diacyl peroxides is only of interest for perbenzoic acid, as the starting material, dibenzoyl peroxide, is commercially available.

Figure 3. Reactions used for the synthesis of peroxyacids

4.2.1. Peroxycarboxylic Acids from Carboxylic Acids and Hydrogen Peroxide

The classical synthesis of peroxycarboxylic acids is the direct, usually acid-catalyzed, equilibrium reaction between carboxylic acids and hydrogen peroxide. With lower aliphatic carboxylic acids, aqueous solutions of peroxycarboxylic acids are obtained, which also contain carboxylic acid and hydrogen peroxide.

The equilibrium mixture is produced by simply mixing the components; the position of equilibrium depends on the molar ratio of the starting materials and on the concentration of the hydrogen peroxide. The equilibrium composition of the system acetic acid – hydrogen peroxide – peracetic acid – water is shown in Table 4 [109].

Equilibrium peracetic acid of this type, with a variable peracetic acid content of up to 40 %, is commercially available.

The reaction can also be carried out in the presence of organic solvents [110], [111]. Catalyst-free equilibrium mixtures can be obtained by the use of acidic, preferably perfluorinated, ion-exchange resins [112]. Strong aliphatic carboxylic acids such as formic acid or trifluoroacetic acid do not require a catalyst, particularly when used in a large excess relative to hydrogen peroxide.

The reaction between a carboxylic acid and hydrogen peroxide can also be carried out in the gas phase over a boric acid – phosphoric acid catalyst [113].

Pure aqueous solutions of peroxycarboxylic acids are obtained from the reaction mixtures by distilling off the peroxycarboxylic acid and water under vacuum [114]. The compositions of azeotropes of some lower peroxycarboxylic acids with water are listed in Table 5.

The production of anhydrous peroxycarboxylic acids can be achieved by three main routes:

1) By extraction of the equilibrium mixture or the pure aqueous solution of peroxycarboxylic acid with organic solvents such as phosphate esters [115], carboxylic esters [116], or chlorinated or aromatic hydrocarbons [117–122]. Residual water in the extracts can be removed by azeotropic distillation.
2) Removal of the water by azeotropic distillation with an organic solvent under vacuum [123–125]. For example, peroxypropionic acid [*4212-43-5*] is obtained in 89 % yield by heating a mixture of hydrogen peroxide, propionic acid, boric acid, phosphoric acid, and dichloroethane at 70 °C for 2 h and then distilling off the dichloroethane – water azeotrope under vacuum [126].
3) By selective absorption of the peroxycarboxylic acid and the corresponding carboxylic acid from the vapor in the distillative production of aqueous solutions of peroxycarboxylic acids in a phosphate ester, followed by desorption with a carboxylic ester [127].

It is not necessary for longer chain, water-insoluble mono- and dicarboxylic acids to be in solution to undergo reaction. In the presence of sulfuric acid the corresponding peroxycarboxylic acids can be obtained in good yields from aqueous suspensions [128–131]. The additional use of a solvent, from which the peroxycarboxylic acid formed will be isolated, is also possible [132]. The isolated compounds are frequently difficult to handle; in these cases they may be stabilized by addition of inorganic salts during the reaction (in situ desensitizing) [133], [134].

Diperoxydodecanedioic Acid [*66280-55-5*], **Desensitized.** Dodecanedioic acid is added to a mixture of 50 % hydrogen peroxide, 96 % sulfuric acid, and trioctylphosphine oxide. After 2 – 3 h at 60 °C the mixture is allowed to cool, diluted with sodium sulfate solution, the pH adjusted to 3.5 with sodium hydroxide, and, depending on the desired peracid concentration, conditioned with sodium sulfate. Diperoxydodecanedioic acid is obtained in 94 % yield.

Aromatic carboxylic acids can be converted to the corresponding peroxycarboxylic acids with methanesulfonic acid as catalyst [135–137]. The use of concentrated sulfuric acid as catalyst has also been described.

Diperoxyisophthalic acid [*1786-87-4*] [138] is obtained in 77 % yield as an 88 % solution from a mixture of 85 % hydrogen peroxide, 96 % sulfuric acid, and isophthalic acid.

4.2.2. Peroxycarboxylic Acids from Carboxylic Anhydrides and Hydrogen Peroxide

The reaction of lower aliphatic carboxylic anhydrides with hydrogen peroxide gives anhydrous solutions of peroxycarboxylic acids in the corresponding carboxylic acid, which is formed by reaction of the water introduced with the hydrogen peroxide with excess anhydride. The reaction is particularly suitable for the synthesis of monoperoxydicarboxylic acids, such as mono-peroxyphthalic acid or monoperoxysuccinic acid, from cyclic anhydrides [139], [140]. Inorganic bases, ammonia, or metal salts can be used as catalysts [141–143].

Monoperoxyphthalic Acid [*2311-91-3*]. The reaction of phthalic anhydride with hydrogen peroxide in 1,2-dichloroethane at 30 °C in the presence of a catalytic amount of ammonia gives, after acidification of the reaction mixture, 90 % monoperoxyphthalic acid in >96 % yield.

Furthermore, the diperoxycarboxylic acids can be obtained under acidic conditions by using a large excess of hydrogen peroxide [144–146].

Decylbutanediperoxycarboxylic Acid [*87458-73-9*]. The reaction of 1 mol of decylsuccinic anhydride in dichloromethane with 3.7 mol of 50 % hydrogen peroxide in the presence of 6.8 mol of 95 % sulfuric acid for 30 min gives decylbutanediperoxycarboxylic acid in 97 % yield with a purity of 98 %.

Explosive diacyl peroxides can be formed as byproducts of the acylation of hydrogen peroxide with lower aliphatic carboxylic acid anhydrides, the amount formed depending on the reaction conditions.

4.2.3. Peroxycarboxylic Acids from Carboxylic Acid Chlorides and Hydrogen Peroxide

The base-catalyzed reaction of carboxylic acid chlorides with hydrogen peroxide is the most important method for the production of aromatic peroxycarboxylic acids, which are difficult to synthesize by other routes [147–150]. Water [151], or water mixed with organic solvents [152], [153], can be used as solvent.

3-Chloroperbenzoic Acid [*937-14-4*] [154]. The reaction of 3-chlorobenzoyl chloride with hydrogen peroxide in alkaline, aqueous dioxane in the presence of $MgSO_4 \cdot 7\,H_2O$ gives, after acidification, 80 – 85 % 3-chloroperbenzoic acid.

The reaction of carboxylic acid chlorides with 85 % hydrogen peroxide in organic solvents such as dichloromethane, diethyl ether, or tetrahydrofuran in the presence of pyridine has also been described. However, the pyridine should not be added in equimolar amounts because of the formation of potentially explosive diacyl peroxides [155], [156].

Peroxydodecanoic Acid [*2388-12-7*]. The reaction of dodecanoyl chloride in tetrahydrofuran with 85 % hydrogen peroxide in the presence of pyridine gives 70 % peroxydodecanoic acid after 20 min reaction in an ice bath.

This method is also suitable for the production of sterically crowded peroxycarboxylic acids [157], [158].

4.2.4. Peroxycarboxylic Acids by Autoxidation of Aldehydes

Aldehydes react with oxygen in a radical chain process to give carboxylic acids. The intermediate peroxycarboxylic acids can be obtained as the main product by appropriate control of the reaction conditions. The reaction can be initiated photochemically or by the use of ozone and it can be catalyzed by metal salts, predominantly cobalt and iron compounds, or by 2,2′-bipyridyl [159–163]. The reaction can be carried out in the vapor phase at standard pressure [164], [165] or in the liquid phase [166], [167].

C_7-Peroxycarboxylic Acid Mixtures. The oxidation of isomeric C_7 aldehydes with oxygen in the presence of 2,2′-bipyridyl at 60 °C gives 62 % of the corresponding peroxycarboxylic acid mixture [168].

The method is suitable for the production of aromatic peroxycarboxylic acids when the autoxidation is carried out at room temperature in carboxylic esters as solvent. Substituted benzaldehydes, however, show considerable differences in reactivity [169].

4.3. Uses

The largest use of peroxycarboxylic acids is in the production of epoxides (→ Epoxides, Chap. 3.). Compounds with an isolated double bond that cannot be oxidized with hydroperoxides or hydrogen peroxide in the absence of a catalyst are epoxidized smoothly and stereospecifically by peroxycarboxylic acids. Cyclic ketones, such as cyclohexanone, are converted to lactones; the production of ε-caprolactone, an important intermediate for the production of polyesters and polyurethanes, is carried out on a large scale. Phenols can be hydroxylated with peroxycarboxylic acids to give dihydroxybenzenes [170–172].

Amine *N*-oxides and -sulfoxides, obtained by reaction of peroxycarboxylic acids with amines and sulfides are used as detergents and in the pharmaceutical industry. The use of peroxycarboxylic acids for disinfection [173–177], in environmental protection, and for bleaching is increasing due to their high oxidizing power and ecological safety. Low-temperature bleaches based on aromatic monoperoxycarboxylic acids

Table 6. Physical properties of some diacyl peroxides

Name	CAS registry no.	Formula	M_r	*mp*, °C	Decomposition temperature, °C	Active oxygen content, %
Diacetyl peroxide	[*110-22-5*]	$H_3C-\overset{O}{\overset{\|\|}{C}}-O-O-\overset{O}{\overset{\|\|}{C}}-CH_3$	118.09	30 (decomp.)	ca. 30	13.5
Acetyl benzoyl peroxide	[*644-31-5*]	$H_3C-\overset{O}{\overset{\|\|}{C}}-O-O-\overset{O}{\overset{\|\|}{C}}-Ph$	180.16	37–39	ca. 40	8.9
Dibenzoyl peroxide	[*94-36-0*]	$Ph-\overset{O}{\overset{\|\|}{C}}-O-O-\overset{O}{\overset{\|\|}{C}}-Ph$	242.23	106–7	ca. 110	6.6
Diisopropyl peroxydicarbonate	[*105-64-6*]	$(H_3C)_2CHO-\overset{O}{\overset{\|\|}{C}}-O-O-\overset{O}{\overset{\|\|}{C}}-OCH(CH_3)_2$	206.19	8–10	35–38	7.8
Acetyl cyclohexylsulfonyl peroxide	[*3179-56-4*]	$H_3C-\overset{O}{\overset{\|\|}{C}}-O-O-\underset{\underset{O}{\|\|}}{\overset{O}{\overset{\|\|}{S}}}-C_6H_{11}$	222.26	35–36	36	7.2

and long chain aliphatic diperoxycarboxylic acids are of interest for laundry detergents [178–182].

5. Diacyl Peroxides

Diacyl peroxides possess the following structural formula:

The best known compound of this type is dibenzoyl peroxide. Both symmetrical (R = R′) and unsymmetrical compounds are known. Furthermore, peroxydicarbonates of type (**3**) and sulfur-containing unsymmetrical diacyl peroxides of type (**4**), where R is an alkyl or cycloalkyl group, are also of interest.

3

4

5.1. Properties

Physical Properties. As a result of the low dissociation energy of the O–O bond (ca. 120–130 kJ/mol [6], [7], [183]), diacyl peroxides are among the best radical-forming compounds. Most diacyl peroxides are low melting solids, which frequently decompose explosively even at low temperature. A summary of physical properties of some important diacyl peroxides is given in Table 6.

Extreme care must be taken when handling diacyl peroxides that have not ben desensitized as they are very sensitive toward shock, impact, and friction (see Chap. 9).

Chemical Properties. The products formed by thermal or photochemical decomposition [184] and the resulting homolytic cleavage of the O–O bond are shown below [185]:

The radicals formed induce further homolytic cleavage, so that the decomposition is autocatalytically accelerated in a chain reaction.

The heterolytic decomposition of diacyl peroxides is catalyzed by strong Lewis acids and highly polar solvents, and leads to rearrangement products [186]:

Acid hydrolysis of a diacyl peroxide gives a mixture of the acid and the peroxyacid [187]:

The reduction of diacyl peroxides leads to various products, depending on the reducing agent. Reaction with trialkylphosphines gives the corresponding carboxylic anhydride [188]; the carboxylic acid is formed with iodide solution, ammonium borohydrides, and with lithium aluminum hydride [189]. The reaction with chromium(II) perchlorate in aqueous ethanol gives a quantitative yield of carbon dioxide and the hydrocarbon [190].

Dialkyl peroxydicarbonates are heat, shock, and impact sensitive. They decompose at low temperature like the diacyl peroxides and at room temperature explosive decomposition may take place, particularly with the lower peroxycarbonates:

The risk of decomposition can be minimized by the use of additives such as iodine, oxygen, or substituted aromatics [191], [192].

5.2. Production

By Autoxidation. Only a few, mainly unsymmetrical, diacyl peroxides are produced by autoxidation. The sulfoxidation of hydrocarbons, leading to acetyl alkyl sulfonyl peroxides, is industrially important [193–195]. The reaction is induced by UV light [196–198] and by lithium and magnesium salts of carboxylic acids [199].

From Peroxycarboxylic Acids. The reaction of peroxycarboxylic acids with acid chlorides is used most frequently for the production of unsymmetrical diacyl peroxides [200–202].

3-Chlorobenzoyl 2-Chlorobutyryl Peroxide [*23128-41-8*]. Treatment of 85 % 3-chloroperbenzoic acid with 2-chlorobutyryl chloride in chloroform at −2 °C in the presence of aqueous sodium carbonate solution leads to the diacyl peroxide in almost quantitative yield with a purity of 90 %.

Chloroformate esters can be converted to acyl alkyl peroxycarbonates by reaction with peroxy acids in the presence of a base [203]:

An analogous reaction with phosgene leads to diacyl diperoxycarbonates [204]:

Diperoxydicarboxylic bis(carboxylic) dianhydrides can be obtained either by reaction of dicarboxylic acid dichlorides with peroxyacids, or by reaction of diperoxydicarboxylic acids with acid chlorides [205]:

Acylation of Hydrogen Peroxide or Sodium Peroxide. Industrially, the most important method for the preparation of symmetrical diacyl peroxides is the reaction of carboxylic acid chlorides or anhydrides with hydrogen peroxide, sodium peroxide, or alkali-metal peroxoborates [206–214].

Diphthaloyl Peroxide [*37051-42-6*]. After 20 h reaction at 25 °C, 78 % diphthaloyl peroxide is

obtained from phthalic anhydride and hydrogen peroxide. About 14 % monoperoxyphthalic acid is formed as byproduct [215].

4,4′-Di-tert-butylbenzoyl Peroxide [*1712-79-4*]. Very pure crystalline product is obtained in quantitative yield by treatment of 4-*tert*-butylbenzoyl chloride with alkaline hydrogen peroxide (without solvent at 30 – 35 °C) in the presence of alkyl sulfonates to reduce the agglomeration of the peroxide particles [216].

For the preparation of hydrolytically sensitive diacyl peroxides, adducts of hydrogen peroxide (e.g., with urea) are used instead of the parent compound [217]. Dialkyl peroxydicarbonates are explosive when concentrated; they can be produced from chloroformate esters and alkaline hydrogen peroxide [218], [219].

Dicetyl peroxydicarbonate [*26322-14-5*] is obtained by treating 35 % alkaline hydrogen peroxide with cetyl chloroformate (hexadecyl chloroformate) at 30 °C, in 98 % yield after recrystallization from carbon tetrachloride [220].

5.3. Uses

Because of their facile thermal decomposition, diacyl peroxides are used, mainly as radical initiators for polymerization (especially diisopropyl peroxydicarbonate), and for cross-linking and hardening of polyester resins. Dialkyl peroxydicarbonates are gaining importance as low-temperature initiators for vinyl chloride polymerization.

The oxidizing power of diacyl peroxides is employed in organic synthesis and in bleaching additives for laundry detergents.

Diacyl peroxides are available commercially only in desensitized form (in solution or as a paste) because of their explosive nature. They should be stored and transported at low temperature.

6. Peroxycarboxylic Esters

The alkyl esters of peroxycarboxylic acids have been known since the beginning of the twentieth century. They can be separated into the following groups, based on the various possible structures:

Esters of peroxycarboxylic acids

Esters of monoperoxydicarboxylic acids

Esters of diperoxydicarboxylic acids

Esters of monoperoxycarbonic acid

Esters of diperoxycarbonic acid

Alkylene bis(peroxy esters) of carboxylic acids

Esters of peroxycarbamic acid

Esters of peroxysulfonic acids

Monoperoxyesters of dibasic acids are best described by the *OO* or the *O* nomenclature, in order to indicate which alkyl group is attached to the peroxy group; hence the compound

is named *OO-tert*-butyl-*O*-isopropyl monoperoxycarbonate.

6.1. Properties

Physical Properties. Peroxycarboxylic esters are thermally unstable because of the low dissociation energy of the O – O bond (ca. 147 – 164 kJ/mol). Therefore, they should be distilled only in exceptional cases and under very mild conditions. Purification by recrystallization or by chromatography is preferable. A summary of the important physical properties of some peroxyesters is given in Table 7.

Peroxyesters can be characterized by means of their refractive index and their density. Qualitative and quantitative determination is possible by polarography, gas chromatography, NMR

Table 7. Physical properties of some peroxyesters

Name	CAS registry no.	Formula	M_r	*mp*, °C	*bp*, °C (kPa)	n_D^{20}	d_4^{20}	Active oxygen content, %

[a] At 25 °C. [b] At 30 °C. [c] d_5^{30}.

and, in particular, IR spectroscopy, with characteristic bands in the carbonyl region at 1750–1820 cm^{-1} and in the fingerprint region between 800 and 900 cm^{-1} [221], [222]. They can also be used for quantitative determination of concentration for kinetic measurements.

Chemical Properties. Esters of peroxycarboxylic acids decompose thermally by radical, ionic, and concerted mechanisms. The most important process in their applications is the thermally or photochemically induced homolytic decomposition of *tert*-butyl peroxycarboxylates to give free radicals [223–225]. This process has been thoroughly investigated and can take place by way of two mechanisms. The actual mode of decomposition is determined by the polar and steric effects of the group R attached to the acyl group [226]:

1) Cleavage of the O – O bond and subsequent reactions

$$(CH_3)_3C-O-O-\underset{\underset{O}{\|}}{C}-R \longrightarrow (CH_3)_3C-O^{\bullet} + {}^{\bullet}O-\underset{\underset{O}{\|}}{C}-R$$

$$R-\underset{\underset{O}{\|}}{C}-O^{\bullet} \xrightarrow{} R^{\bullet} + CO_2 \quad \xrightarrow{+HX} R-COOH + X^{\bullet}$$

$$(CH_3)_3C-O^{\bullet} \xrightarrow{} (CH_3)_2CO + H_3C^{\bullet} \quad \xrightarrow{+HX} (CH_3)_3C-OH + X^{\bullet}$$

2) Simultaneous cleavage of the O – O and the C – R bonds

$$(CH_3)_3C-O-O-\underset{\underset{O}{\|}}{C}-R \longrightarrow (CH_3)_3C-O^{\bullet} + CO_2 + R^{\bullet}$$

The kinetics of thermal decomposition of tertiary peroxyesters is influenced by the structure of the peroxyester [227] and by the polarity of the solvent [228], [229]. The stability decreases in the following order: *tert*-butyl > *tert*-amyl > tert-octyl > cumyl. In addition, the stability depends on the degree of α-substitution of the carboxylic acid moiety [230], [231]. Primary and secondary peroxycarboxylic esters decompose rapidly by a concerted mechanism to give a carboxylic acid and a carbonyl compound [232], [233]:

The radical-induced decomposition, in which a radical adds to the O – O bond resulting in cleavage, is usually undesired because fewer radicals are formed than expected for complete decomposition of a peroxycarboxylate. From one radical and one peroxyester molecule, which should normally give two radicals, only one radical is formed together with an ester molecule [234]:

$$R''^{\bullet} + R_3C-O-O-\underset{\underset{O}{\|}}{C}-R' \longrightarrow R_3C-O^{\bullet} + R''-O-\underset{\underset{O}{\|}}{C}-R'$$

Radical-induced decompositions are therefore not as effective as thermal homolysis, but can serve to extend the temperature range for the use of peroxycarboxylic esters.

Tertiary peroxyesters are more stable towards radical-induced decomposition than diacyl peroxides. This stability is more pronounced for peroxyesters that have an α-hydrogen atom or an unsaturated alkyl group [235].

Metal ions, especially copper(I) ions, catalyze the decomposition of peroxyesters [236], [237]:

$$R'-\overset{\overset{O}{\|}}{C}-O-O-R + Cu^{+} \longrightarrow R'-\overset{\overset{O}{\|}}{C}-O^{-} + R-O^{\bullet} + Cu^{2+}$$

This reaction is of preparative use in the acyloxylation of compounds with reactive C – H bonds.

The ionic decomposition of peroxycarboxylic acids occurs with rearrangement [238], [239]:

Peroxycarboxylic esters undergo hydrolysis much more readily than the corresponding carboxylic esters, with formation of carboxylic acids and hydroperoxides:

$$R_3C-O-O-\underset{\underset{O}{\|}}{C}-R' \xrightarrow{H_2O} R_3C-O-OH + R'-\underset{\underset{O}{\|}}{C}-OH$$

For the determination of peroxycarboxylic acids, conventional iodometric titration [240] is not usually applicable because it is always accompanied by an acid-catalyzed decomposition

that does not consume iodine. The reaction of the peroxycarboxylic ester with sodium ethoxide or methanolic potassium hydroxide, followed by either iodometric titration of the resulting hydroperoxide [241], or metal-catalyzed iodometric titration [242] is more suitable.

6.2. Production

Peroxycarboxylic esters cannot be produced by direct esterification of peroxycarboxylic acids. All of the literature methods start from the corresponding hydroperoxide. The most stable and, therefore, most readily accessible peroxyesters are the tertiary peroxycarboxylic esters. The most important production processes include the reaction of hydroperoxides with carboxylic acids, carboxylic acid halides, anhydrides, and *N*-acylimidazoles (Fig. 4).

From Hydroperoxides and Carboxylic Acids. Hydroperoxides can be esterified with carboxylic acids to give peroxyesters. The reaction is generally catalyzed with *p*-toluenesulfonic acid and pyridine [243], dicyclohexyldiimide [244], [245], or phosphate esters [246]. The reaction probably takes place via an intermediate activated carboxylic acid derivative. Mineral acids or boron trioxide are also suitable as catalysts for the production of peroxyesters of C_2-C_{10} aliphatic carboxylic acids and peroxyesters of aromatic carboxylic acids [247]. The water of reaction can be removed by azeotropic distillation with toluene, benzene, or cyclohexane.

From Hydroperoxides and Carboxylic Acid Halides. The reaction of carboxylic acid halides, in particular the chlorides, with hydroperoxides is the most important and industrially most frequently employed method for the synthesis of peroxycarboxylic esters. The process is usually carried out with high selectivity under Schotten–Baumann conditions in aqueous [248–251] or aqueous – organic media. Ether or a chlorinated hydrocarbon is used as the organic solvent [252–255]. In addition to the use of uniform starting materials, mixtures of carboxylic acid chlorides and/or hydroperoxides are also used, since the resulting mixtures of peroxyesters possess special properties for their application as polymerization initiators [256], [257].

tert-Butyl Peroxyoctadecanoate

[*2123-89-9*]. Octadecanoyl chloride (0.165 mol) is added at 10 °C to a mixture of 0.2 mol *tert*-butyl hydroperoxide in petroleum naphtha. Subsequently, 0.2 mol of pyridine is added to this mixture in such a way that the temperature does not exceed 15 °C. After standing for 40 min at room temperature, the mixture is shaken with 10 % hydrochloric acid. The product crystallizes from the organic phase, is washed with water and dried; yield 96 %.

The reaction takes place smoothly at low temperature in the presence of organic bases, preferably pyridine [258–265], but triethylamine [266–268], 2,6-dimethylpyridine [269] or 1,4-diazabicyclo[2.2.2]octane [270] have also been used. This method permits the use of an anhydrous system and is therefore suitable for acyl chlorides that are poorly soluble in aqueous media. In this way peroxyesters of carbamic acids, carbonic acid [271], and acetylene carboxylic acids can be prepared.

Di- or tetraperoxyesters can be produced both from the corresponding dicarboxylic acid dichlorides or tetracarboxylic acid tetrachlorides and hydroperoxides [272–274], as well as from bishydroperoxides and carboxylic acid chlorides [275]:

Primary and secondary alkyl peroxycarboxylic esters are best prepared from the alkali metal salts of the corresponding hydroperoxide [276–

280], since they are not readily accessible by other methods.

From Hydroperoxides and Carboxylic Anhydrides. Hydroperoxides, alkyl metal peroxides, or alkyl nonmetal peroxides can also be acylated by carboxylic anhydrides:

The reaction is carried out in the presence of alkali-metal hydroxide solution, organic bases such as pyridine, or alkali-metal acetates [281], [282]. This method is particularly suitable for the synthesis of dicarboxylic acid mono-*tert*-alkyl peroxyesters [283], [284]. The use of mineral acids as catalysts is only possible for acid-stable hydroperoxides.

tert-Butyl Monoperoxysuccinate [*28884-42-6*]. *tert*-Butyl hydroperoxide (0.13 mol) and 0.06 mol pyridine are added in succession to 0.12 mol succinic anhydride at 45–55 °C. After 15 min the mixture is cooled, extracted with chloroform, and the extract washed with hydrochloric acid and water. The product is isolated in 83 % yield by distillation from the dried organic phase.

Alkylperoxy organogermanes, -stannanes, -silanes, and -stibines are cleaved heterolytically at the O–M bond by carboxylic anhydrides [285–288]:

The corresponding dicarboxylic mono-*tert*-butyl peroxyesters can be obtained by treatment with 0.5 N sulfuric acid or by introducing dry hydrogen chloride [289].

From Hydroperoxides and *N*-Acylimidazoles. The acylation of alkylhydroperoxides with the very reactive *N*-acylimidazoles, available from carboxylic acids and *N,N′*-carbonylimidazoles, is particularly useful when the corresponding acyl chloride cannot readily be obtained pure [290–292]. Isolation and purification of the *N*-acylimidazole intermediate is not necessary. The reaction can be carried out from imidazole in a one-pot process [293]:

This method is of limited use for the production of peroxycarboxylic esters derived from carboxylic acids containing a C=C double bond [294].

Other Methods. The acid-catalyzed reaction of hydroxycarboxylic acids with hydrogen peroxide in ether leads to cyclic peroxycarboxylic esters [295]:

Esters of peroxychloroacetic acid are obtained by acidolysis of dialkyl peroxides with chloroacetic acid [296]:

Figure 4. Reactions used for the synthesis of peroxyesters from hydroperoxides R′−OOH.

Ketenes and isocyanates add hydroperoxides under neutral or weakly acidic conditions to give the peroxyesters of carboxylic or carbamic acids [297–299]:

This method is particularly suitable for the production of base-sensitive peroxycarboxylic esters. The reaction of triperoxyborates, produced from borate esters and hydroperoxides, with carboxylic acids leads similarly to the corresponding peroxycarboxylic esters [300]:

The acid-catalyzed reaction is carried out in aromatic or cycloaliphatic solvents such as benzene, toluene, or cyclohexane. However, the reaction is not suitable for primary hydroperoxides.

6.3. Uses

The most important industrial application of peroxyesters is in the initiation of polymerization reactions, and as hardeners for resins. The more reactive types (e.g., *tert*-butyl or cumyl peroxypivalate) are used mainly as initiators for the polymerization of ethylene or vinyl chloride. *tert*-Butyl perbenzoate is used predominantly as a hardener for polyester resins.

The usual commercial products are of technical grade or are product mixtures that have been desensitized by the addition of an organic solvent (aliphatic hydrocarbons, carboxylic esters). Frozen peroxide emulsions can be stored safely and exhibit very good storage stability [301].

Peroxycarboxylates play an important role in preparative organic chemistry in, for example, inter- and intramolecular epoxidation of olefins in the presence of copper salts [302]. The peroxyesters react with strong nucleophiles, such as Grignard reagents or phosphines, with transfer of the alkoxy group. The copper-catalyzed acyloxylation of C−H bonds occurs by a radical mechanism. In this way, α-acyloxy derivatives of olefins, ethers, and thioethers

can be obtained [303]. Thermal homolysis of peroxyesters in protic solvents can be used for the decarboxylation of carboxylic acids.

7. α-Oxyperoxides

α-Oxyperoxides possess the structural element

where X = −H, −R, and Y = −H, −R, −OH, −OR. The substituents X and Y may also be part of a cyclic group. A selection of possible structures is given in Table 8.

Table 8. Structure and nomenclature of α-oxyperoxides

Substituents		
X	Y	Name
H	H	α-hydroxyhydroperoxide
H	R	α-alkoxyhydroperoxide
H	OH	geminal bishydroperoxide
H	OR	α-hydroperoxyperoxide
R	H	α-hydroxyperoxide
R	R	α-alkoxyperoxide
R	OR	geminal diperoxide, peroxyketal

Cyclic alkoxyperoxides of the type

are known as ozonides. α-Oxyperoxides are unstable and highly reactive and therefore capable of numerous reactions.

7.1. Properties

Physical Properties. The stability of α-oxyperoxides varies widely depending on the structure, and range from explosive to being stable up to the melting or boiling point. Physical properties of some selected compounds are listed in Table 9.

Chemical Properties. As the chemical behavior of α-oxyperoxides depends markedly on the structure, only a few typical reactions are described here.

The thermolysis of α-oxyperoxides leads to a complex mixture of products [304]. Dicyclohexylidene diperoxide and tricyclohexylidene diperoxide give C_{12} or C_{15} cycloalkanes which are not readily accessible by other routes, as well as lactones with 12- or 15-membered rings [305], [306].

The decomposition of dimeric cyclopentanone and cyclohexanone peroxides (dicyclopentylidene diperoxide, dicyclohexylidene diperoxide) in the presence of a Cu(I) catalyst in aqueous hydrochloric acid leads to 5-chlorovaleric acid and 6-chlorocaproic acid, respectively, in high yield [307], [308].

Cycloaliphatic α-oxyperoxides decompose to form open-chain dicarboxylic acids in the presence of iron or copper salts as catalysts [305], [309], whereas dehydration of these compounds leads to cyclic geminal alkylidene triperoxides (1, 2, 4, 5, 7, 8-hexaoxycyclononanes).

Heating α-oxyperoxides in water causes elimination of hydrogen peroxide to give the dimeric α,α'-dihydroxyperoxides which can be dehydrated to give ozonides [310]:

Ozonides (cyclic α-alkoxyperoxides) give a multitude of products upon thermal or radical induced decomposition [311]. The reactive species is the carbonyl oxide (**6**), formed from the primary ozonide (or 1,2,3-trioxolane) (**5**):

Table 9. Physical properties of some α-oxyperoxides

Name	CAS registry no.	Formula	M_r	*mp*, °C	*bp*, °C (kPa)	Active oxygen content, %
2-Chloro-1-hydroperoxy-cyclohexanol	[*15250-08-5*]		166.71	76		9.6
α,α′-Dihydroxydicyclo-hexyl peroxide	[*2407-94-5*]		230.30	69–71		6.9
α-Hydroperoxy-α′-hydroxy-dicyclohexyl peroxide	[*78-18-2*]		246.30	78		13.0
α,α′-Bishydroperoxydicyclo-hexyl peroxide	[*2699-12-9*]		262.30	82–83		18.3
Dicyclohexylidene diperoxide	[*183-84-6*]		228.29	127–129		14.0
Tricyclohexylidene triperoxide	[*182-01-4*]		342.43	93		14.0
Dicyclopentylidene diperoxide	[*311-38-6*]		200.23	95–98		16.0
Diisopropylidene diperoxide	[*1073-91-2*]		148.16	132		21.6
2,2-Bis(*tert*-butylperoxy)-propane	[*4262-61-7*]		220.31		69–70 (2.0)	14.5
2,2-Bis(*tert*-butylperoxy)-butane	[*2167-23-9*]		234.34		50 (0.27)	13.7
1,1-Bis(*tert*-butylperoxy)-cyclohexane	[*3006-86-8*]		260.37		52–54 (0.02)	12.3
Ethylene ozonide (1,2,4,-trioxolane)	[*289-14-5*]		76.05		18 (2.1)	21.0
Isobutene ozonide (3,3-di-methyl-1,2,4-trioxolane)	[*22409-33-2*]		104.10		42–42.5 (18.0)	15.4
Tetramethylethylene ozonide (3,3,5,5-tetramethyl-1,2,4-trioxolane)	[*15592-50-4*]		132.16	133–134		12.1

The primary ozonide (**5**) is unstable and generally not isolable [312], [313]. In contrast, ozonides of structure (**7**), with the exception of the simplest representatives such as ethylene ozonide which is explosive, are stable compounds that can be isolated. They only tend to decompose spontaneously under the catalytic influence of heavy metals [313].

Ozonides can be reduced to aldehydes and oxidized to carboxylic acids [304].

Figure 5. Reactions of aldehydes with hydrogen peroxide, alkyl hydroperoxides, and peroxycarboxylic acids

7.2. Production

Three main routes exist for the production of α-oxyperoxides:

1) Autoxidation of ethers, acetals, aldehydes, or alcohols
2) Addition of hydrogen peroxide, alkyl hydroperoxides, or peroxycarboxylic acids to carbonyl compounds
3) Ozonolysis of unsaturated compounds

α-Oxyperoxides by Autoxidation. Autoxidation is not suitable for the preparation of α-oxyperoxides because the reaction usually leads to mixtures of products. Ethers are readily oxidized by atmospheric oxygen to yield ether hydroperoxides, from which the explosive polymeric ether peroxides are formed [186], [314]:

Acetals are easier to autoxidize than ethers. Dimers of structure **10** are formed from 1,3-dioxolanes (**8**) via the hydroperoxide (**9**), when R = H or CH_3 [315]. Bulky groups impede the dimeriza-tion. Autoxidation of vinyl-1,3-dioxolanes (R = −CH = CH_2) leads to heterocyclic α-oxyperoxides (**12**), via formation of an unstable allyl peroxide (**11**) intermediate [316].

2-Hydroperoxy-2-isopropyl-1,3-dioxolane [*34594-19-9*] (R = $-CH(CH_3)_2$) is obtained in good yield by the reaction of 2-isopropyl-1,3-dioxolane with atmospheric oxygen at 75 °C [317].

Autoxidation of alcohols gives mixtures of α-hydroxyhydroperoxides and α,α'-bishydroperoxyperoxides [318–320]:

2-Hydroperoxy-2-propanol, the primary oxidation product of 2-propanol, decomposes in the presence of water to give hydrogen peroxide and acetone. This process is employed indus-

trially for the production of hydrogen peroxide (→ Hydrogen Peroxide) [321], [322].

The autoxidation of aldehydes proceeds via intermediate α-hydroxyalkyl peroxycarboxylates to give the corresponding peroxycarboxylic acids:

This reaction is used industrially for the production of peroxyacetic acid from acetaldehyde.

α-Oxyperoxides by Addition of Hydrogen Peroxide, Alkyl Hydroperoxides, or Peroxycarboxylic Acids to Carbonyl Compounds. Aldehydes react with hydrogen peroxide to give mixtures of α-hydroxyhydroperoxides (**13**) and α,α'-dihydroxyperoxides (**14**). Aldehydes react with alkylhydroperoxides under acid catalysis to form α-hydroxyperoxides (**15**), which react with excess hydroperoxide to form peroxyacetals (**16**) [323], [324]. With peroxycarboxylic acids, aldehydes and ketones form α-hydroxyalkyl peroxycarboxylic esters (**17**), which may also be obtained by acylation of α-hydroxyhydroperoxides [325]. These reactions are summarized in Figure 5.

In the presence of concentrated sulfuric acid, aldehydes react with hydrogen peroxide to form cyclic geminal alkylidenedi- and triperoxides (1,2,4,5-tetroxanes and 1,2,4,5,7,8-hexaoxacyclononanes) [326].

Treatment of ketones with hydrogen peroxide gives a multitude of products, most of which arise from rearrangements. For example, the following compounds are formed from cyclohexanone:

α-Hydroperoxycyclohexanol

α, α-Dihydroperoxycyclohexane

α, α′-Dihydroxydicyclohexyl peroxide

α-Hydroperoxy-α′-hydroxydicyclohexyl peroxide

α, α′-Dihydroperoxydicyclohexyl peroxide

Dicyclohexylidene diperoxide (3,6-dicyclohexylidene-1,2,4,5-tetroxane)

Tricyclohexylidene triperoxide (3, 6, 9-tricyclohexylidene-1, 2, 4, 5, 7, 8,-hexaoxacyclononane)

α,α'-Dihydroperoxydicyclohexyl Peroxide

[*2699-12-9*]. Treatment of cyclohexanone with hydrogen peroxide in acetonitrile in the presence of perchloric acid results in formation of α,α'-dihydroperoxydicyclohexyl peroxide in good yield. The compound can be recrystallized from hexane.

The α-oxyperoxides of acetone [327], cyclohexanone [305], [326], [328], [329], methyl ethyl ketone [327], and acetylacetone [330] have been studied in detail. Ketones react with alkyl hydroperoxides to give peroxyketals, whereby the peroxy hemiketals normally cannot be isolated [32], [327], [331], [332]:

Reaction of α,α'-dihydroperoxyperoxides with ketones leads to formation of cyclic geminal alkylidenedi- and triperoxides, which are used as starting materials for the synthesis of macrocyclic dienes [305], [306], [333–335].

α-Oxyperoxides by Ozonolysis. In the ozonolysis of olefins, other α-oxyperoxides in addition to the ozonides are formed [304], [336]. The reaction is of little preparative use as it is generally not very selective for α-oxyperoxides,

and gives defined compounds only for tetrasubstituted olefins [311].

7.3. Uses

α-Oxyperoxides are mainly used as vulcanization accelerators, cross-linking agents [337], [338] and hardeners, in particular methyl ethyl ketone peroxide and methyl isobutyl ketone peroxide, as well as cyclohexanone peroxide and various peroxyketals. In combination with transition metal salts a wide temperature range can be covered (e.g., thermal hardening of polyesters), so that suitable catalyst systems are available for various materials [339–342].

Ozonides are used as disinfectants [343]. Ozonolysis is applied industrially using fatty acids, e.g., in the production of nonanedioic acid and nonanoic acid from oleic acid [344], [345], or of decanedioic acid from cyclodecene [346]. α-Oxyperoxides are commercially available only in desensitized form because of their explosiveness. Phosphates, dibutyl phthalate, and aliphatic hydrocarbons are typical additives.

8. α-Aminoperoxides

In addition to the hydroperoxy or peroxy group, α-aminoperoxides bear a nitrogen atom on the same carbon atom; both functional groups may be part of a ring.

8.1. Properties

Physical Properties. The physical properties of some α-aminoperoxides are listed in Table 10. Their stability varies widely, ranging from high shock and impact sensitivity with the lower homologues to a thermal stability up to the melting point.

Chemical Properties. Some typical reactions of α-aminoperoxides are as follows [347]:

The unstable 1-amino-1-hydroperoxycyclohexane reacts with ketones to form cyclic α-aminoperoxides. With aqueous ammonia in alcohol and catalytic amounts of sodium tungstate, cyclohexanone oxime is formed. Acylation gives a dimeric product with elimination of hydrogen peroxide. Catalytic decomposition in the presence of iron leads to cyclohexanone together with small amounts of caproic acid and its amide. Cyclohexanone, together with ε-caprolactam, is also the pyrolysis product of 1-amino-1-hydroperoxycyclohexane.

1,1′-Peroxydicyclohexylamine rearranges, both thermally and photochemically, to decane-1,10-dicarboxylic acid imide; byproducts include ε-caprolactam and cyclohexanone. These reactions are shown in Figure 6.

Thermolysis at >400 °C leads mainly to 11-cyanoundecanoic acid.

Radical decomposition with iron or copper salts gives caproic acid amide and cyclohexanone.

ε-Caprolactam is formed from 1,1′-peroxydicyclohexylamine in good yield by treatment with sodium methoxide in methanol.

Table 10. Physical properties of some α-aminoperoxides

Name	CAS registry no.	Formula	M_r	*mp*, °C	*bp*, °C (kPa)	Active oxygen content, %
1-Amino-1-hydroperoxycyclohexane	[*24075-24-9*]		131.18	57–58 (decomp.)		12.2
1,1′-Peroxydicyclohexylamine	[*21842-28-4*]		211.30	40–42	94–97 (0.05)	7.6
1,1′-Peroxydicyclopentylamine	[*21842-27-3*]		183.25	22–23		8.7
2,2′-Peroxydiisopropylamine	[*24075-03-4*]		131.18		50 (1.6)	12.2
2,2′-Peroxydiisobutylamine	[*24075-04-5*]		159.23		66–68 (1.6)	10.1
1-Amino-1-*tert*-butylperoxy-cyclohexane	[*24829-66-1*]		187.28		36–38 (0.03)	8.5
1-Cyclohexylamino-1-hydroperoxy-cyclohexane	[*2808-61-9*]		212.31	88–89		7.5
1-Hydroperoxy-1-azocyclohexane	[*32140-97-9*]		225.31	73–75		7.1

Figure 6. Reactions of 1,1′-peroxydicyclohexylamine

8.2. Production

α-Aminoperoxides can be produced by the same methods as α-oxyperoxides. Autoxidation is important only for Schiff's bases [348]. High yields of α-aminoperoxides are obtained by the Mannich reaction of amines with formaldehyde and hydroperoxides:

$$R_2NH + CH_2O + R'-OOH \xrightarrow{-H_2O} R_2N-CH_2-O-O-R'$$

The most useful synthetic method is the reaction of carbonyl compounds with hydrogen peroxide in the presence of ammonia or primary amines [349–358]:

The initially formed α-aminoperoxides are frequently not isolable and react further with the carbonyl compound to give 1,2,4-dioxazolidines.

Cyclopentanone forms 1,1′-peroxydicyclopentylamine, whereas 1-aminohydroperoxides are formed from large-ring ketones.

1-Amino-1-hydroperoxycyclohexane [*24075-24-9*]. A solution of 30 % H_2O_2 is added to a mixture of methanol, ammonia, and cyclohexanone with stirring at 0 °C. The precipitated solid is removed by filtration and the crude product obtained in 88 % yield [359]. The use of alkyl hydroperoxides instead of hydrogen peroxide gives 1-aminoperoxides.

8.3. Uses

α-Aminoperoxides are important intermediates in the synthesis of ε-caprolactam [360–363], of cyclohexanone oxime [347], of derivatives of terminal dicarboxylic acids [347], [349], and in the production of nylon-12 from cyclohexanone [364]. More recently, they are also being considered for use as initiators in polymerization of styrene [365], as disinfectants [366], and as antimalarial agents [367].

9. Safety Measures

9.1. Hazards

Organic peroxides are frequently very unstable compounds which can decompose spontaneously and explosively under thermal or mechanical stress. Such decomposition can be caused by shock, impact, friction, or by the catalytic effect of impurities. Organic peroxides are therefore subject to the regulations for explosives [368].

Specific safety and protective measures must be observed when working with organic peroxides [369], [370]. To reduce the hazards involved, commercially available peroxides are usually desensitized by addition of inert solids or liquids. Typical desensitizing agents are water, inert solvents (aliphatic and halogenated hydrocarbons, phthalate and phosphate esters, acetals), and inert inorganic solids (sulfates, phosphates, borates, silicates, carbonates). Therefore peroxides are available in solid, liquid, or paste form. Investigation of the hazards associated with organic peroxides involves a wide range of test methods which are described in the relevant legal regulations. In Germany BAM is responsible for conducting and evaluating such tests. Similar institutions exist in other countries [371]. In the most important tests the following properties of peroxides are investigated:

1) Detonation or deflagration ability (BAM 2″ steel tube test)
2) Shock sensitivity (BAM falling hammer test)
3) Friction sensitivity
4) Heat sensitivity under defined confinement in a steel tube (Koenen test)
5) Explosive energy in a lead block (Trauzl method)

The explosive range of peroxide-containing mixtures can be displayed graphically, as shown in Figure 7 for the $H_2O_2-HCOOH-H_2O$ system [372], [373]. For industrial applications, knowledge of explosive ranges is essential, in particular for reactions in which performic or peracetic acid is generated in situ. In these cases the aqueous phase that is usually present is extremely explosive.

Figure 7. Explosive range (hatched area) for H_2O_2–HCOOH–H_2O.

The explosive range can be investigated, for example, by 2″ steel tube tests. Passage through this range must be avoided during a reaction by appropriate process control.

9.2. Transportation and Storage

Organic peroxides are subject to the regulations for dangerous materials [374]. The establishment of the maximum permitted ambient temperature for storage and transportation is based on the SADT (self-accelerating decomposition temperature), above which peroxide decomposition is self-accelerating. The SADTs of some commercial peroxides are listed in Table 11. Organic peroxides and their formulations must be transported and stored at a temperature significantly below the SADT. For thermally very unstable peroxides maximum transportation temperatures are specified.

In Germany, the "Safety Precautions for Organic Peroxides" are applied for storage [370]. National transportation regulations are based on the recommendations for the transportation of dangerous goods by the United Nations. The UN has reexamined the classification of organic peroxides and new regulations have been introduced [375]. Organic peroxides are assigned to the hazard groups A to G by means of a flow diagram, which also indicates the permitted amount for a given container and container type. Following the new regulations, some peroxides with a low active oxygen content may be exempted. Until then, the following dangerous goods regulations are valid for the Federal Republic of Germany, within which the organic peroxides are assigned mainly to Class 5.2:

Road transportation:	GGVS with Appendices A and B, ADR
Transportation by rail:	GGVE/RID
Maritime:	GGVSee with Appendix, IMDG
Air Freight:	ICAO Technical Instructions, IATA-DGR

9.3. Handling

Safety glasses and gloves must be worn when handling organic peroxides. Protective clothing is required when working with larger amounts of peroxides [369]. In the event that skin or eye contact with peroxides occurs, the afflicted area should be immediately rinsed with water for a sufficiently long period (at least 15 min). Contaminated clothing should be removed. A physician or eye specialist should be consulted without delay.

Cleanliness at the workplace is an essential prerequisite for working safely with peroxides because even small amounts of contaminants such as ash, dust, or traces of heavy metals could lead to decomposition. The containers and equipment employed must be stable against peroxides and must not promote decomposition. Suitable materials are glass, porcelain, earthenware, stainless steel, and certain plastics such as teflon or polyethylene. When setting up apparatus suitable precautions must be taken as decomposition can lead to a considerable pressure increase. Often it is best to work with open containers. Peroxide samples removed from their original containers should not be returned because of the risk of contamination. Preliminary experiments should be carried out with small quantities of material. Furthermore, peroxides should only be added in small amounts, in order to avoid high local concentrations. Transferring and weighing of peroxides must be carried out carefully, as even slight friction or impact with a spatula or a scoop could cause an explosion with the more sensitive compounds.

Spills of water-soluble peroxides can be cleared up without risk by the use of large amounts of water. Compounds that are insoluble in water must be diluted and desensitized

Table 11. Self-accelerating decomposition temperature (SADT) of commercial peroxides

Peroxide	CAS registry no.	Supplied form	SADT, °C
tert-Butyl hydroperoxide	[*75-91-2*]	70 % in water	88
		solution in phosphate	ca. 65
Cumene hydroperoxide	[*80-15-9*]	80 % water	80
Di-*tert*-butyl peroxide	[*110-05-4*]	technical grade (liquid)	79–80
2,5-Dimethyl-2,5-bis(*tert*-butylperoxy)-hexane	[*2618-77-1*]	liquid	82
Dicumyl peroxide	[*80-43-3*]	technical grade (powder)	88
		40 % (powder with chalk)	> 70
Peracetic acid	[*79-21-0*]	40 % in acetic acid/H_2O	55
		15 % in acetic acid/H_2O/H_2O_2	60
Dibenzoyl peroxide	[*94-36-0*]	aqueous, technical grade	68
		technical grade (flakes)	ca. 50
		50 % in plasticizer	52
		50 % in silicone oil	63
Diacetyl peroxide	[*110-22-5*]	25 % solution in phthalate	ca. 35
tert-Butyl perbenzoate	[*614-45-9*]	technical grade	ca. 60
Diisopropyl peroxydicarbonate	[*105-64-6*]	40 % solution in phthalate	ca. 5
Acetyl cyclohexanesulfonyl peroxide	[*3179-56-4*]	water-damp granules	ca. 15
		28 % solution in phthalate	ca. 5
Methyl ethyl ketone peroxide	[*1338-23-4*]	40 % solution in phthalate	63
		50 % solution in phosphate	ca. 65
Methyl isobutyl ketone peroxide	[*37206-20-5*]	60 % solution in phthalate	64
Cyclohexanone peroxide	[*12262-58-7*]	moistened with water	ca. 50
		50 % solution in phosphate	ca. 50
2,2-Bis(*tert*-butylperoxy)butane	[*2167-23-9*]	50 % solution in phthalate	63

with sufficiently large amounts of appropriate solvents. After being absorbed in an inert material they should be destroyed immediately. The hazard associated with moist peroxides increases considerably with increasing dryness. Before absorbing these materials they should therefore be dampened sufficiently with water. Small quantities of peroxides can be disposed of most simply by incineration. For larger quantities, information can often be obtained from the producer.

10. Toxicology

Organic peroxides generally possess a pronounced effect on body tissue, and marked damage must be expected at the site of direct contact. Nevertheless, there are many peroxide compounds whose effect on the organism is less pronounced or that lead to no noticeable effect on health. The chemical structure and physical properties such as water solubility, fat solubility, and vapor pressure, as well as the type and composition of the formulation (concentration, solvent, additives), can be important for penetration of human tissue and in reactions with cell compartments and macromolecules. In contrast, the influence of UV and ionizing radiation is not so predominant in the effect of organic peroxides on the mammalian organism, and is not comparable with the formation and effect of endogeneous radicals produced by radiation.

The main effects associated with contact with peroxides are local irritation and burns of the skin, the mucous membranes of the eyes and the respiratory tract [376] (see Table 12).

Local tissue reactions may appear immediately following exposure or may only become apparent after a few days. Healing of the damaged tissue is frequently very slow and irreversible effects in the tissue are posssible. In the skin, irritation appears in the form of reddening (erythema) and swelling (edema), as well as burns (necrosis, corrosion), which are characterized by severe degenerative changes and scarring. In direct contact with the eye, even very small amounts of peroxides can cause inflam-

Table 12. Acute toxicity data for organic peroxides

Compound	CAS registry no.	Irritation *		Acute Toxicity	
		Skin	Eye	LD_{50}, mg/kg (rat, oral)	LC_{50}, (4 h, inhalative)

* Degree of irritation: – no effect, (+) weak, + slight, + + moderate, + + + severe (caustic). ** LD_{50} value after dermal application (rabbit).

mation of the conjuctiva, nacreous opacity of the cornea, or loss of the eye [377]. This can often be avoided by immediate and intensive rinsing with water. Nevertheless, this procedure must be carried out for a sufficiently long period, especially with contamination by solid or powdery material, as even strongly diluted solutions can cause irritation. For example, dry benzoyl peroxide possesses a smaller irritant effect than a 10 % aqueous solution.

Inhalation of the vapor of volatile peroxides also leads to irritation or burns of the mucous membranes of the eye or the upper respiratory tract (nose, throat, bronchia). Inflammation of the respiratory tract or even lung edema can result from prolonged exposure [378].

Sensitization of the skin by peroxides has been observed mainly with dibenzoyl peroxide [379], [380]. In animal experiments methyl ethyl ketone peroxide and cyclohexanone peroxide exhibited ambiguous positive results [381], [382], whereas diperoxydodecandioic acid was clearly negative [383]. Acute poisoning may result from the inhalation and ingestion of organic peroxides, but in practice the hazard of resorptive effects (systemic toxicity) is low. After swallowing, peroxides are moderately toxic (see Table 12). In animal experiments, the acute toxicity for substances administered orally, dermally and by inhalation was characterized by tremors, decrease in muscle tone, clonic convulsions, hyperactivity, and dyspnea. Furthermore, irritation, hemorrhages, and inflammation were detected in the mucous membranes of the small intestine or respiratory tract [384], [385]. After chronic exposure to peroxy compounds, effects on the general condition, on the red blood cells, and impairment of the immune system in the blood (SH groups, peroxidase activity) towards oxidative reagents (oxidative stress) may appear [386]. Data exist only for a few organic peroxide compounds with respect to their carcinogenic, mutagenic, or reproductive toxicological potential. These data are not always sufficiently unambiguous to allow estimation of the risk associated with chemicals of this group. Observations on humans are not available. In long-term studies with rats and mice no substance-related tumors appeared after oral or subcutaneous application of benzoyl peroxide for up to two years [387].

After repeated application of organic peroxides to the skin of mice (skin painting studies) none of the tested compounds were found to be an absolute carcinogen. In two-stage ex-

periments on the chemical carcinogenicity (initiating or promoting properties in the formation of tumors), none of the compounds examined showed a complete carcinogenic or tumor-initiating activity. Nevertheless, a number of compounds (benzoyl peroxide [388–390], *tert*-butyl hydroperoxide [391], lauroyl peroxide [391], peracetic acid [392], perbenzoic acid [393], chloroperbenzoic acid [394], and methyl ethyl ketone peroxide [381]) were found to promote skin tumors in mice and hamsters. For example, with dimethylbenzanthracene as tumor initator, subsequent treatment of the skin of mice with benzoyl peroxide led to skin carcinomas, whereas with benzoyl peroxide alone only hyperpigmentation, formation of skin scales, and a low level of hyperplasia of the skin was found [388–390]. When UV radiation was used as a tumor initiator, weak promoting activity was exhibited by methyl ethyl ketone peroxide [394], but not by benzoyl peroxide [395], [396]. Investigations of the mechanism of action of organic peroxides in vivo and in vitro showed an influence on the activity of the calcium-dependent protein kinase [397] and enzymes of the cytochrome P 450 peroxidase system [398], [399], as well as the participation of glutathione (SH groups) in the reduction [400] of the exogenously administered peroxides. In more recent investigations, the activation of oncogenes has been reported [401].

Testing of organic peroxides for mutagenicity by means of experiments with bacterial assays (*Salmonella typhimurium, Escherichia coli*) showed essentially no increased rate of mutation (dilauroyl peroxide [393], benzoyl peroxide [393], dibenzoyl peroxide [402], di-*tert*-butyl peroxide [393], peracetic acid [393]). However, both positive and negative results have been reported for *tert*-butyl hydroperoxide [393], [403], dicumyl peroxide [393], [404], monoperoxysuccinic anhydride [405], and disuccinoyl peroxide [404]. Direct interaction with DNA in the form of single strand breaks [406], [407] or as sister chromatid exchanges (SCE) [408] could be demonstrated by in vitro experiments. DNA transformation with *Bacillus subtilis* bacteria was observed with disuccinoyl peroxide [409], but not with di-*tert*-butyl peroxide [410]. In the mouse lymphoma forward test *tert*-butyl perbenzoate acted as a weak mutagen [408].

Reproductive toxicology experiments have been carried out with three-day-old chicken embryos. Cyclohexanone peroxide, cumene hydroperoxide, methyl ethyl ketone peroxide, benzoyl peroxide, acetylacetone peroxide, *tert*-butyl perbenzoate, dicumyl peroxide, and lauroyl peroxide led to embryotoxic effects. Malformation was only observed to a small extent [411].

Abstract

The article contains sections titled:

1. Introduction
2. Physical and Chemical Properties
3. Production
3.1. Production Processes
3.1.1. Delayed Coking
3.1.2. Fluid Coking
3.1.3. Flexicoking
3.2. Calcination
3.2.1. Rotary Kiln Calciner
3.2.2. Rotary Hearth Calciner
4. Uses
4.1. Green Petroleum Coke
4.2. Calcined Petroleum Coke
5. Quality Aspects
5.1. Green Coke
5.2. Regular Calcinate
5.3. Needle Coke
6. Environmental and Safety Aspects
6.1. Green Coke
6.2. Calcined Petroleum Coke

The petroleum coke production started about 80 years ago and will reach the 100 × 10^6-t/a level in the next years. The yearly increase rates are up to 10%.

Characteristics, localization, and production methods including the Delayed Coker process of petroleum coke are shown. The world market profile for petroleum coke is presented, and the amount and prices of the petroleum coke species, “green coke”, “regular calcinate”, and “needle coke” are given. Particular interesting is the production process of green coke, which is increasingly used in power generation, and the production of metallurgical coke for steel processes (blast furnace). The use of regular calcinate for the carbon anode in the aluminium production stagnates because of the impetuous development of the aluminium recycling. Likewise, the needle coke has only marginal increase for the production of graphite electrodes used in electric-arc furnaces by steel processes. The reason is the rapidly reduced consumption of electrodes/t steel due to process modifications.

The environmental and safety aspects are addressed and the available results are shown.

[Top of Page]

1. Introduction

Petroleum Coke is a grayish-black solid residue with a high carbon content. It is obtained during the thermal conversion process in crude oil processing. Although petroleum coke has been known for more than 100 years, both production and its specific application and improvement have seen an increasing boom only during the last 80 years. It is anticipated that

up to the year 2010 ~100 × 10^6 t/a of petroleum coke will be produced in oil refineries. The majority of this quantity is obtained in delayed coking plants. In other facilities for processing crude oil residue components, investments are made at present in flexicoking units, whereas fluid cokers are still run but hardly set up in new production.

[Top of Page]

2. Physical and Chemical Properties

Physical Properties. Petroleum coke is a grayish-black solid matter of very varied composition. Generally, a distinction is made between petroleum coke from fluid and flexicoking plants and that obtained from delayed coking processes. The petroleum coke from delayed cokers is also called *green coke*. The fluid and flexicokers supply a fine-grained petroleum coke that has a high level of isotropy and in general an ash content of between 1 and 4 wt %. The grain consistency of these cokes is high, the content of volatile combustible matter (VCM) is low and hardly exceeds 5 wt %. In contrast petroleum coke from delayed cokers is normally characterized by both high porosity and anisotropy. The VCM content is between 7 and 14 wt %; it is only set to < 5 wt % for needle coke production. The ash content is low, generally < 0.1 wt %. The bulk density of normal-quality petroleum coke is around 0.8 – 0.9 g/cm^3. If however, the feed stream to the delayed coker is rich in high molecular asphalt, a non-porous isotropic petroleum coke is the result which has a high bulk density of 1.2 – 1.4 g/cm^3. The formation of this *shot coke* quality can be counteracted by machine adjustment.

Another basic form of petroleum coke is *calcined coke*. Calcined coke is a product derived from green coke. Here, the hydrocarbons have been removed by heating green coke under reducing conditions in kilns or hearths to over 1300 °C. Classification of petroleum coke types derived from delayed cokers into:

- Shot coke
- Sponge coke (fuel coke)
- Sponge/honeycomb coke (regular or anode-grade coke)
- Needle coke (graphite or premium coke)

is not defined precisely [1]. A differentiation with regard to isotropy and crystal structure is logical. There is a graded transition from:

> Shot coke (mainly isotropic; amorphous, no crystal structures formed; hardly any pores)

to

> needle coke (high anisotropy; regular crystal structures, containing a great number of fine pores, crystallite size of the order of 4 – 7 nm).

Petroleum coke results from a thermal cracking and polymerization reaction. After going through the mesophase a solid crystalline form is formed, which, contrary to indications [2] does not plastify again. Coking only occurs in the VCM particles contained. If their fraction exceeds 15 %, the release of this petroleum coke at high temperatures gives the impression of a plastic state of aggregation. By treating petroleum coke with steam and hot water, those components that are slightly water soluble can be washed and steamed out of the petroleum coke.

Chemical Properties and Composition. Under normal conditions petroleum coke has a low reactivity. At higher temperature (up to 1400 °C, calcination conditions) an expansion of the crystallite size up to 2.5 – 3.5 nm takes place because of the cracking of side chains. At the same time the original hydrogen content of approx. 3.5 wt % is reduced to below 0.1 wt %. Under graphitization conditions (ca. 2900 °C) good crystallized forms of petroleum coke (needle coke character) are transformed into graphites. These graded changes in quality of petroleum coke with temperature demonstrate most suitable the structure, character, and classification of the product.

The dominant element in petroleum coke is carbon. The hydrogen content is around 3.5 wt %. An overproportional amount of sulfur and nitrogen reaches the petroleum coke from the feed components (S content of petroleum coke 0.1 – 5 wt %; N content 0.2 – 1.5 wt %). The V and Ni contents of the feed streams remain entirely in the petroleum coke. The Na, Ca, and Mg content in the petroleum coke is the sum of the content of these cations in the crude oil and of their concentration in the cutting water (Section Green Coke). According to the 21st ATP (Adaptation of Technical Progress of the European Substance Directive) and CONCAWE, product dossier no. 93/105 [3], petroleum coke is considered a nondangerous product. The level of polycyclic aromatics in petroleum coke is about 250 mg/kg. Benzo[*a*]pyrene makes up about 25 mg/kg. The amount of heavy metals apart from V and Ni is insignificant (< 1 mg/kg). In general the quality of the feed components and the production conditions determine the quality of the product.

[Top of Page]

3. Production

In 2004, about 60 × 10^6 t of petroleum coke were produced worldwide, which are available in the market. This is about two-thirds of the production rate. One third will be revalorized by the producer [4]. The market-available petroleum coke is about 10 % of the quantity of blast-furnace coke (hard coke) produced from hard coal [5]. More than 95 % of the petroleum coke is produced in delayed cokers, about a third of the feed streams is incurred as petroleum coke. Residues and crack components (see Section Delayed Coking) are used in delayed cokers in more than 65 refineries. Due to the reaction conditions only about 5 – 10 wt % of the feed material is converted into petroleum coke in case of fluid and flexicokers. The number of these production units is much lower. In 1996 13 fluid cokers and 5 flexicokers were in production worldwide. Most petroleum coke is produced in North America, followed by South America and Western Europe. Anode grade is the most important product with regard to margin and value. Table 1 and 2 list the worldwide locations for

petroleum coke and projects in construction [4].

3.1. Production Processes

3.1.1. *Delayed Coking*

Coking is an effective way for an integrated refinery to process the residues of crude oil. Coking processes are normally carried out to minimize coke and maximize liquid products. The first atmospheric coking processes were started in 1928. Coking, in general, has become more important over the years because tradtional heavy fuel oil demand has declined and the demand for lighter products has increased. This has made it more attractive to convert the heavy fuel oil components into better marketable light, clean components. The present major source of production of marketable coke is the delayed coking process developed by Standard Oil. Conventional delayed coking is shown in the flow diagram in Figure 1. A delayed coke complex is depicted in Figure 2.

Figure 1. Flow sheet of delayed coking

a) Fractionator; b) Furnace; c) Coke drum; d) Crusher; e) Coke dewatering bin; f) Water tank; g) Coke – water pit

Figure 2. Photograph of a refining delayed coker complex: furnace, coke drums, fractionator, and dewatering bins

The refinery residues are heated in a furnace (b) up to about 485 – 500 °C. After passing a fractionator tower where middle distillates are topped off, they are fed into one of the coking chambers. The energy gained in the furnace passages is sufficient to release the cracking reaction in the filling time of the coking chamber (delayed coking). The reaction zone is also called mesophase, because the transition from liquid residue molecules to solid crystalline coke structure occurs here. The pressure in the coking chamber can be varied between 2 and 6 bar. In the furnace, steam is dosed to the residue to inhibe the formation of coke. The vapors in the coking chamber — gases, naphtha, middle distillates, and a heavy coker gas oil — are led to the fractionator for separation, fractionated and forwarded for stabilizing post-treatment. The heavy coker gas oil is recycled as coker feed or is used in other refinery processes: e.g., after go-fining (a hydrogenation process) as feed for fluid catalytic cracking [6].

While one coking chamber is being filled in the cycle time, the other chamber is emptied. A typical volume of a modern coke drum is about 1000 m^3 with a range in diameter of 5 to 8 m and in height of 25 to 35 m. After steaming and cooling of the coke chambers, the coke is removed by drilling and cutting with high pressure water (up to 300 bar pressure). The green coke obtained is conveyed to its application after the draining step: either as fuel of feed for calcining. Table 3 shows the different green coke qualities in relation to use.

Table 3. Green coke qualities in relation to use

	Heating medium	Regular calcinate feed	Needle coke feed
Sulfur content, wt %	> 2	1.0 – 3.0	0.1 – 0.8
V/Ni content, mg/kg	200 – 500	50 – 200	< 50
Ca/Na content, mg/kg	50 – 300	20 – 100	< 50
VCM, wt %	9 – 14	7 – 9	5 – 7

The following components can be used as feed for delayed cokers [7]:

1. Crude residues (atmospheric or vacuum),
2. Crack components (visbroken tar, cycle oil, decant oil, or thermal crack tar),
3. Deasphalting residues,
4. Coal oils, and
5. Used plastic materials (recycling)

The products of delayed coking processes are (basis: vacuum residue or crack components):

1. Gas/LPG (ca. 13 wt %)
2. Naphtha (ca. 11 wt %)
3. Middle distillate (ca. 45 wt %)
4. “Green coke” petroleum coke (ca. 31 wt %)

Delayed coking is carried out in order to free refinery from the product “heavy fuel oil” which is not easily marketable. In terms of investment delayed coking is a much cheaper technology than flexicoking or hydrocracking (factor 3 to 5). A further argument in favor of delayed coking can be the revalorization potential for the carbon products “regular calcinate” or “needle coke” produced. Moreover, delayed coking shows good product results, which, however, like all thermal conversions, have “middle distillates” as main product.

Figure 3 shows the product yields for the North Sea crude “Brent”. All thermal conversion processes reduce the crude residues higher than middle distillates, especially the delayed coker unit.

Figure 3. Product yields with thermal conversion processes

Goal of nearly all delayed coker units is to minimize coke yield and obtain as many distillate fractions as possible. However, when the objective is to produce green coke that shall serve as raw material for higher quality coke products (regular calcinate and needle coke) a specific feed optimum must be found that by no means results in a minimum coke yield.

The distillate yields and thus the capacities of delayed coking can be increased by [7], [8]:

1. Preconversion of feed components [6]
2. Addition of light middle distillate to the feed stream
3. High coke drum outlet temperature / high coker furnace outlet temperature (COT)
4. Low operating pressure
5. Low fresh feed: recycle ratio
6. Addition of coil steam

Some quantitative effects are shown in Figure 4.

Figure 4. Relationship between plant operating conditions and plant yield; parameters: coke drum pressure = 2.5 bar; feed/recycle ratio = 1 : 1.3; coke drum outlet temperature = 440 °C [9]

The following technical improvements have been achieved for the production of petroleum coke in modern delayed coking plants. They result in increased plant reliability, improved work safety and better coke quality as well as increased production capacity [10-13]:

1. Onstream decoking (allows decoking of one of the four furnace coils during current production)
2. Homogeneous petroleum coke quality (requires temperature and recycle ratio ramps over the cycle time to adjust continuous coking conditions)
3. Optimum coke chamber filling (requires mass balance of feed and products and measurement of the coke chamber level)
4. Batch computerization (allows automatic checking and starting of operation steps without losing time)
5. Automatic coke cutting with vibration alarms at coke drum wall
6. Automatic hydraulic coke drum bottom head
7. Combination tool for drilling and cutting
8. Hydraulic feed line
9. Hydraulic coke drum bottom head closing

With these technical measures the cycle time for delayed coking can be reduced from about 24 to 12 h [14-17]. The time required for different steps in typical 12-h and 24-h coking cycles is listed in Table 4.

Table 4. Time allotted for different steps in typical 12-h and 24-h coking cycles

Operation step	Time, h	
	24-h cycle	12-h cycle
Switch drum	0.5	a

Steam out to fractionator	0.5	a
Steam out to blowdown	1.0	
Slow water cooling	1.0	b
Full water rate	5.0	b
Drain water and remove top head	3.5	1.5
Drop bottom head and feed line	0.5	0.5
Hydraulic decoking	4.0	2.0
Replace heads and feed line	1.0	0.5
Steam purge and pressure test	1.0	0.75
Drum heat up	4.0	2.25
Slippage allowance	2.0	1.0
Total	24 h	12 h

[a] Total time for both operation steps: 0.5.
[b] Total time for both operation steps: 3.0.

3.1.2. *Fluid Coking*

The continuous fluid coking process utilizes fluidized solids technique developed for fluid catalytic cracking (⟶ Oil Refining), except that no catalyst is used. A flow scheme is shown in Figure 5.

Figure 5. Flow sheet of fluid coking

a) Reactor; b) Scrubber; c) Burner; d) Air blower

Residue is feed to the reactor (a). The cracking reactions occur at 500 – 550 °C in a fluidized bed of coke particles. The coke formed in the reactor flows continuously to the heater, where it is heated up to 600 – 650 °C by partial combustion in a second fluidized bed. Part of the heated coke particles are returned to the reactor to supply the energy to the endothermic crack reactions and to maintain the reactor temperature. The remainder of the coke after cooling is removed as a stream of fine particle “petroleum coke”. Fluid coke is only occasionally used for production of anodes [18].

3.1.3. *Flexicoking*

The flexicoking process combines fluid coking with gasification. A flow scheme of flexicoking is shown in Figure 6.

Figure 6. Flow sheet of flexicoking

a) Reactor; b) Scrubber; c) Heater; d) Gasifier; e) Cyclones; f) Airblower

Flexicoking is a residue conversion process that combines coke gasification with conventional fluid coking. Three fluidized beds are in operation at the reactor, heater, and gasifier. Shrinking markets for the coke obtained in substantial amounts as byproduct of delayed coking and fluid coking due to restrictions of sulfur emission encouraged the development of the flexicoking process. In flexicoking most of the coke produced is converted to low-Btu fuel gas in the gasification reactor. This fuel gas can be desulfurized to approximately the equivalent of a 0.25 wt % sulfur fuel oil. Thus, particularly for feed stocks with a high metal and sulfur content, flexicoking can be an advantage, because it produces marketable liquid products plus fuel gas.

Thermal conversion of the feed takes place in the reactor (a) where the feed is atomized through a series of nozzles into a bed of fluidized coke particles. Coke occurs in a thin film on the fluidized particles within the bed. The coke bed is fluidized by the product vapors and by stripping steam injected at the bottom of the reactor. Typical bed temperatures are 510 – 540 °C. Vapor products from the conversion reactions in the bed go overhead through cyclone separators, which remove most of the entrained coke and return it to the reactor bed. The cyclone outlets discharge the vapor product directly into a scrubber (b) where heavy liquid is used to scrub out the remaining coke dust and condense unconverted high boiling fractions. The dust laden liquid is recycled as “slurry cycle” to the reactor with the feed. The scrubbed vapor is sent to the coker fractionator, where the stream is split into gas, naphtha, distillate and heavy gas oil streams. Coke produced in the reactor is gasified by steam and air in the gasifier (d), which operates at a bed temperature of approximately 955 °C. The heater (c) serves as a surge vessel and transfers heat from the gasifier overhead gas to coke which in turn supplies the heat of reaction in the reactor. The heater bed temperature is approximately 610 °C. Coke is continuously circulated between the three vessels to transfer heat and maintain vessel inventories. Heat for the endothermic cracking reactions in the reactor is supplied by coke combustion in the gasifier. In addition to the coke fines recovered from the heater overhead gas, product coke can be withdrawn from the heater bed. All liquid or gas streams require further treating [19].

3.2. Calcination

About 25 % of the petroleum coke derived from delayed coking processes is stabilized by calcination. Calcination includes

the elimination, burning, and coking of water and higher boiling hydrocarbons contained in petroleum coke. Finally a carbon product remains that contains sulfur and nitrogen plus small amounts of vanadium, nickel, sodium, calcium, iron, and silicon.

At present calcining is carried out at about 40 calciner sites (see Table 5). While the calciners in North America are usually run by independent companies or attributed to aluminum works, the calciners in other regions are production units of the refineries.

Calcining is carried out in rotary kiln and rotary hearth plants. While the rotary kiln largely predominates in America, equal amounts of kiln and hearth plants are used in Europe.

In both types of calcining complexes the water and VCM contents of green coke are eliminated by heating up to 1400 °C. The heat required for calcining the green coke is primarily provided by burning the VCM released from the coke calcination process. Combustion air is admitted to the calciner. In normal operation only the quantity of air sufficient for complete combustion of the VCM release from the coke is added, no free oxygen occurs in the off-gas.

3.2.1. *Rotary Kiln Calciner*

The rotary kiln calciner (Fig. 7) consists of a rotating heated steel tube (e) with a refractory lining. Because of the gradient and the rotation of the tube, the green coke descends in the calciner and heat flow rises in countercurrent. The calcined coke leaving the kiln is discharged into a rotary cooler (f). The flue gases are cooled in a waste-heat boiler (i) and cleaned in an electrostatic precipitator (j).

Figure 7. Schematic of the rotary kiln calciner

a) Screen; b) Crusher; c) Weigh feeder; d) Green coke sampling; e) Rotary kiln; f) Cooler; g) Sampling calcined coke; h) Incinerator; k) Stack

3.2.2. *Rotary Hearth Calciner*

The rotary hearth calciner (Fig. 8) was originally developed by the Wise Coal and Coke company. Green coke charged at the periphery of the hearth travels around the calciner (b) in a series of concentric paths. At the completion of each revolution the coke is moved by a rabble arm set in the roof into the next concentric path. This process is repeated, until at the final rabble, the coke is discharged into the soaking pit. From the soaking pit the coke can be discharged into a rotary cooler (c). During normal operation the retention time for the coke in the hearth and soaking pit is approximately 2 h [20].

[Top of Page]

4. Uses

Worldwide annual consumption of industrial carbon is about 25×10^6 t/a, excluding metallurgical coke (see Table 6). Two-thirds of this margin is calcinate from petroleum coke [21], [22].

Table 6. Production of industrial carbon (World 1994)

Carbon Products	Production, t/a	Average product value, $/t	Market value, 10^9 $/a
From petroleum coke			
Carbon anodes	9×10^6	700	6.3
Söderberg anodes	4×10^6	500	2.0
Graphit electrodes	1.1×10^6	5500	6.05
Reduction medium/TiO2-Process	2×10^6	600	1.2
Partly from petroleum coke			
Carbon cathodes	6×0^5	1300	0.78
From other products			
Carbon black	8×10^6	1500	12
Activated carbons	5×10^5	3000	1.5
Carbon construction materials, etc.	1×10^5	800	0.8
Electrographite powder	8×10^4	1500	0.12
Carbon fibers	6×10^4	7×10^4	4.2
Synthetic diamonds	50	15×10^6	0.75
Total	~ 24×10^6		~ 36

Figure 9 shows the world market profile for petroleum coke in 1999 [23]. The relations are the same as now: More than 70 % of petroleum coke is burned as fuel.

Figure 9. World market profil for petroleum coke

4.1. Green Petroleum Coke

More than 70 % of the petroleum coke produced is marketed as green coke. This green coke is a cheap fuel used primarily in the cement industry or for electricity generation. Qualities with a sulfur content below 1.5 % are used as a supplementary substance for hard coke production, if the coal has too high a VCM content. In addition, this green coke is used in the production of carbides, too.

There is increasing use of petroleum coke as addition for metallurgical coke [24] primarily used in blast ovens for producing iron.

Green coke is sold worldwide. The biggest trans-shipment center with some million tons of storage capacity is Rotterdam.

4.2. Calcined Petroleum Coke

Anode-Grade Coke (Regular Calcinate). Most calcined petroleum coke is used for production of carbon and Söderberg anodes (Table 6). Moreover, as aluminum production with Söderberg anodes is declining due to environmental aspects, the requirement will shift more to carbon anodes. The coke quality required is called anode grade coke or regular calcinate [21].

Worldwide aluminum production was 22.6×10^6 t in 2004; 60 % of the aluminum production capacities are located in North America and Europe. Aluminum production is expected to increase about 9 % per year. With a consumption of about 430 kg regular calcinate per tonne of aluminum the worldwide regular calcinate demand in the aluminum industry is more than 10×10^6 t/a. The recycling rate for aluminum is increased to about 30 % [25], [24]. Therefore, the world aluminum consumption is higher than 30×10^6 t/a.

The Alcoa Test (Alcoa = biggest Al producer in the world) with “inert” anodes is currently running. Inert anode means: Reduction without carbon. The success of this test will be sceptically criticized because of process economics and Al purity [24].

Regular calcinate in the fraction 0.2 – 1.0 mm is used for titanium dioxide production. More than 70 % of the worldwide TiO_2 production of 4×10^6 t/a is produced using the Chloride Process. This process needs about a third of that using rutil as reduction medium.

Needle Coke. Petroleum coke is also used for the production of graphite electrodes (Table 6). The quantity employed for this purpose has been stagnating for years. This high-grade quality is called needle coke. Although the proportion of electrosteel production in overall steel production is steadily increasing, a series of optimizing steps have continuously reduced the electrode consumption per tonne of steel. Whereas in 1985, 7 kg electrode material was needed per tonne of steel, modern furnaces can manage with less than 2 kg/t. For this reason the consumption of electrodes worldwide is still around 1.1×10^6 t/a (2005).

Needle coke qualities are used as part components for cathode blocks, sidewall blocks, and ramming pastes for the production of aluminum. A further application of this quality is its use in steel carburization.

A series of special industrial uses of carbon material, which are negligible in terms of quantity, make use the thermal and chemical resistance, the thermal and electrical conductivity, and graphitization of petroleum coke. The amount required for this purpose is normally covered by carbon dust separated during the production of carbon anodes and electrodes.

[Top of Page]

5. Quality Aspects

The quality of coke is chiefly influenced by the feed material used in the petroleum refining. Of second and third importance are the coking and the calcining conditions. Structure, density and VCM contents can vary significantly as can the sulfur, metals, and ash contents.

Over the last years an international standardization of testing methods for carbon materials has been developed. ISO, EN, DIN, or ASTM specifications or drafts exist for nearly all parameters. Standardization has almost been achieved even in the case of coefficient of thermal expansion measurement (CTE), for a long time tested by proprietary methods of electrode manufacturers. The situation that national standards (ASTM, DIN) are incorporated in the international ISO specifications makes itself positively noticeable.

5.1. Green Coke

Compared with coal, the petroleum coke has

- higher energy content
- lower ash residue
- lower VCM content (volatile combustion matter).

The quality of normal green coke mainly used as fuel is defined by the sulfur content. Additional parameters are the water content (for the quantity calculation), the ash, and VCM content. In the case of green coke used for higher grade products the level of metals and the grain size distribution are further quality criteria.

5.2. Regular Calcinate

The quality of calcined petroleum coke produced in Europe is superior to that produced in other continents. Due to authority requirements and improvements in efficiency, regular calcinate in Europe has undergone a quality improvement towards needle coke: the sulfur contents, reactivity results, and CTE figure are lower, and the vibrated bulk density is higher. Some non-European manufacturers are already producing similar qualities. Typical European quality characteristics are listed below. The figures in brackets refer to quality requirements outside Europe [26-29].

Sulfur content, wt %	max. 1.7 (3)
Ni/ V content, ppm	max. 120 – 150 (200)
Na/ Ca/ Si content, ppm	max. 100
Vibrated bulk density (1 – 2mm), g/cm^3	0.80 – 0.85 (0.75 – 0.80)
Air reactivity (1 – 1.4 mm), wt %/min	max. 0.15
CO_2 reactivity (1 – 1.4 mm), wt %	max. 12
CTE factor (carbon anodes), 10^{-6} /°C	3.5 – 4.5 (5.5)
Hydrogen content, wt %	0.05 – 0.09
Real density, g/cm^3	2.06 – 2.10
Ash content, wt %	0.05 – 2.20
Crystallite size L_c, nm	2.5 – 3.2
Specific electric resistivity, μΩ m	460 – 520
Grain stability, wt %	min. 70
Dust forming factor, wt %	max. 0.02
Water/oil content, wt % (from antidust additive)	max. 0.3

Except for the SO_2 emission the sulfur content only has slight side effects on aluminum electrolysis.

The goal in aluminum electrolysis is to have a small consumption of anodes with a good electricity yield. Good production results are 95 % electricity yield with an anode consumption of < 410 kg per tonne aluminum. These figures can be reached if the anodes meet the specifications for:

1. High carboxy (CO_2) reactivity residue
2. High air reactivity residue
3. Low specific electric resistivity
4. Low thermal conductivity

With the capacity increase of aluminum smelters, larger anodes have come into use. Cracking of the anodes due to thermal shock has been observed occasionally in these cases. Good thermal shock resistance of the anodes is therefore desirable. Improvements in thermal shock behavior will occur if CTE, the Young's modulus, and the flexural strength are decreased, and the thermal conductivity is increased.

5.3. Needle Coke

In the production of steel by the arc furnace process about 1×10^6 t/a graphite electrodes are needed. Charging stock for the electrodes are needle coke (about 85 %), and pitch binder for backing and impregnation. Needle coke is the highest grade product of calcinated petroleum coke. Because of the massive thermal and mechanical stresses in the arc furnaces, the highest demands are placed on the electrode properties. Moreover, subsequent modified graphitization due to the baking of the electrodes result in additional stricter quality requirements.

Modern lengthwise graphitization is considerably more economic and only needs a third of the time required by conventional Acheson graphitization (⟶ Carbon – Manufacture), but the more drastic reaction conditions demand superior qualities from the needle coke. For this reason needle coke specifications have greatly improved over the last 15 years. Room for further improvement seems only marginal.

For needle coke the chemical properties (low contents of S, Ni, V, Na, Ca, Si) and the following physical characteristics must be optimum:

1. High real density and high vibrated bulk density
2. High grain stability and high proportion of coarse grain
3. Low coefficient of thermal expansion

In addition the microcrystalline structure is important, because all physical parameters depend on it. A high level of anisotropy, regular micropores between the graphite lattice plane, a high crystallite size, especially after graphitization, and crystal areas, which contrary to graphite have to be offset against each other, are indispensable. In order to obtain these needle coke qualities, three manufacturing areas have to be optimized:

1. Feed selection for delayed coking (low sulfur and low metal residues with high contents of 3, 4, and 5-ring aromatics and low asphaltene content)
2. Delayed coking conditions (longer cycle, higher recycle ratio, right furnace coil out temperature ramp)
3. Calcination conditions (heating rate and final calcination temperature)

The quality analysis of needle coke is special because two parameters are specified that can only be analyzed after graphitization: The CTE and the puffing factor; i.e., the irreversible lengthwise expansion during graphitization (requirement: < 2 %). The quality comparison has been more complicated up to now by the fact that the preparation, graphitization, and measurement of CTE were proprietary company methods. Standardization however is nearly concluded (last step: proposal of CTE–DIN method, an English translation exists as ISO draft) [30].

The quality requirements of electrodes depend on the electrode diameter and also on the type of arc furnace (d.c. or a.c. operation). That is why different types of needle coke are available. Some properties of “super premium” and “intermediate premium” qualities are listed in Table 7. The CTE values refer to the measuring range 20 – 200 °C after preparation and graphitization according to the DIN method.

Table 7. Typical range of needle coke types

Property	Super Premium needle coke	Intermediate Premium needle coke
CTE (20 – 200 °C), 10^{-6}/°C	0.35	0.6
Sulfur content, wt %	0.2 – 0.4	0.4 – 0.6
Vibrated bulk density, g/cm^3	0.83 – 0.90	0.83 – 0.90
V/ Ni content, mg/kg	< 10	< 10
Real density, g/cm^3	2.13 – 2.15	2.13 – 2.14
H content, wt %	0.03 – 0.05	0.03 – 0.05

There are ongoing tests to produce “ultra premium” needle coke with CTE levels of 0.25 × 10^{-6}/ °C. Production constancy, possible production quantity and processing characteristics of this quality still need to be evaluated.

An additional challenge in the use of electrodes in the arc furnace process is the design and production of the nipples (screw connections between the individual electrodes). Thorough pilot tests, test runs, and a guaranteed production constancy for needle coke are the basis for delivery agreements.

[Top of Page]

6. Environmental and Safety Aspects

6.1. Green Coke

Although green coke contains polycyclic aromatics their total concentration of about 250 mg/kg is below the critical level of 1000 mg/kg. Also the content of the key component benzo[*a*]pyrene (ca. 25 mg/kg) is not critical. Green coke is therefore classified as a nontoxic substance [3].

No classification and labeling as regards toxicity, carcinogenicity, flammability, and environmental effects is required. Contents of Ni, V, Na, Ca, and Fe originating from the crude oil residues used as feed are accumulated in green coke. The levels amount to ca. 10 – 500 mg/kg. Small amounts of metals and anions are introduced with the cutting water, which makes up 5 – 15 % of green coke (cutting water content: Na, Ca, Cl, SO_4^{2-}). Other heavy metals (Hg, Cd, Pb, Cr, Cu, Co, As) are not traceable (level < 1 mg/kg). Hydrocarbons and metals in green coke cannot be elutriated with water (S4 eluate method).

The following classification is employed for the combustion and explosion behavior [measurement of Deutsche Montan-Technologie (DTM), mining test circuit, Dortmund]:

Combustion behavior	BZ 3 (local combustion or glowing without spreading)
Glow temperature	300 °C
Ignition temperature	700 °C
Dust explosiveness	contents > 60 g/m^3 and with ignition source of > 10 000 J

Green coke is normally stored in open piles with side walls as protection against the wind. In order to reduce the dust

discharge, green coke piles are sprinkled with water. The potential dust emission is visibly improved by means of dosing antidust additives (polyacrylate types) to the sprinkling water.

The general explosive boundary value at work of 6 mg/m^3 for fine dust concentrations is to be complied with.

6.2. Calcined Petroleum Coke

All hydrocarbons in green coke are eliminated by calcination. The remaining hydrogen content is < 0.1 %. Therefore, no polycyclic aromatics are traceable. The content of S, N, and metals is virtually unchanged. With water, only part of the salt content of the cutting water can be elutriated. No classification and labeling is required.

Due to the dryness of the calcinate, irritation of eyes and throat by the dust is possible. The general boundary value at work (max. 6 mg/m^3 for fine dust concentration) is to be complied with.

Calcined coke is usually stored in closed silos or bins to keep the material dry. To reduce dust formation, the calcinate is sucked out during transport and loading and the dust held back by filter stations. Sprinkling the calcinate with residue parts of 0.2 – 0.4 wt % (old process) or an aqueous emulsion of dust binder prevents environmental problems from dust. The dust forming factor ("R+D-Carbon"-method) must be < 0.02 wt %. The combustion and explosive behavior of calcined coke presents no problem:

Combustion behavior	BZ1 (no combustion)
Glow temperature	no glowing up to 450 °C
Ignition temperature	no ignition up to 850 °C
Dust explosive	no

Since no combustible dust – air mixture is formed, calcined dust is a material that has no security zone classification (zone 11) and does not come under the risk management regulation.

1. Dosage Forms as Drug Delivery Systems [1–3]

Contemporary dosage forms are designed to achieve a safe and therapeutically effective response each time they are administered within appropriate regimens that reflect accurate doses and dosing intervals. Thus, drug products are drug delivery systems that accomplish the prescriber's intent and which complete the Physician – Patient – Pharmacist triad when used "as directed" in a compliant manner.

Each type of dosage form involves several concepts and components:

1) The active ingredient (drug) in correct and accurately measured amount (dose) and of appropriate purity
2) Nontherapeutic ingredients (adjuvants, excipients) needed for the safe and effective preparation and delivery of the drug moiety
3) Unit manufacturing processes (technologies) designed so as to ensure that the product elicits safe and effective responses each time (e.g., tablet-to-tablet) and for each batch
4) Container or packaging designed for patient convenience and to maintain stability and therapeutic performance
5) Comprehensive quality assurance to safeguard the drug during shelf-life, during appropriate storage and use

The *drug moiety* must be available in pure form with an appropriate particle size, crystalline structure, and physicochemical form and in an accurate amount.

Appropriate *excipients* must be selected to insure stability (e.g., antioxidants, antimicrobial preservatives, buffers), accurate dose delivery (diluents), and product performance. The latter excipients include disintegrating agents for compressed tablets and polymers for enteric coatings. Some excipients are processing aids, e.g., glidants to ensure effective flow of granules from hoppers and lubricants for tablet compression. Attention must also be given to excipients for patient acceptance and compliant use (flavors, colors). Excipients should be compatible with the drug moiety and should not form complexes with the drug that lessen therapeutic availability during production and storage. Similarly, excipients must not affect the stability of the drug product or any of its components.

Production technologies must guarantee reliable therapy, i.e., equally safe and effective responses each time a dosage form is administered. The technologies depend on the dosage form in question. They must not be deleterious to product stability, nor should they decrease the availability of the drug moiety upon administration.

The equipment used also varies in size from small laboratory units for research and development to large-scale manufacturing units. Each manufacturer utilizes a pilot plant or scale-up operation in which development pharmacists and engineers have to transform laboratory-scale batches to full production scale without altering product performance, accuracy, precision, or stability. The major operations utilized in the manufacture of drug products are listed below:

1) Dissolution
2) Filtration
3) Dispersion or wetting of solids
4) Homogenization
5) Lyophilization
6) Encapsulation of powders (hard gelatin shells and soft gelatin capsules)
7) Comminution of solids, including micronizing to ultrafine particle size
8) Blending of powders
9) Granulation of powders
10) Compression and tabletting
11) Coating of powders, granules or tablets (pan coating, compression coating, air suspension coating)
12) Microencapsulation (coacervation, etc.)
13) Heating and cooling of liquids and semisolids
14) Molding (suppositories)
15) Drying
16) Pressurized filling (of aerosols)
17) Sterilization (steam autoclave, ethylene oxide autoclave, membrane filtration, radiation, laminar flow hood)

The *design of the package*, including selection of appropriate container and sealing materials, also affects the performance of the drug product. The container must assure stability throughout the product storage and use. Its shape and size must insure ease of use and efficient delivery to foster patient compliance.

Throughout the preparation of the dosage form, *quality assurance* must be guaranteed by good manufacturing practice (e.g., cleanliness, record keeping, process control). Quality assurance also includes quality-control testing of raw materials and final products to comply with relevant specifications. In-process testing (e.g., of tablet hardness and weight) is performed at critical stages of production. Each process must be validated to show that it accomplishes its intended function(s) with the same results from batch-to-batch.

During the development of a new dosage form *stability testing* is performed to verify that degradation does not occur during processing and storage. A shelf life is determined for each product and expiration dates are obtained.

Product labeling insures product identity, provides appropriate storage and dating information, and cites necessary warnings.

Bioavailability [4–6] In order to achieve a therapeutic response after administration, the drug moiety must be made available to the body and efficiently released from the dosage form. For example, a compressed tablet designed for oral administration must first disintegrate in the gastrointestinal tract. The drug from the resulting particles must dissolve in the gastrointestinal fluids and be absorbed into the blood circulation for distribution throughout the body. The drug may, however, bind to plasma proteins in the blood. The drug is metabolized in the liver but a certain proportion is excreted unchanged through the kidney. Absorption, distribution, metabolism, and excretion (ADME) oc-

cur simultaneously and at different rates that depend on the drug involved; the sex, race, age, and state of health of the patient; and other factors (e.g., presence of other drugs).

For a given drug dose to be effective, a sufficient amount must be absorbed (i.e., be available to the blood) at an appropriate rate. The kinetics of the subsequent distribution, metabolism, and excretion processes must ensure that the concentration of the drug at the site of action reaches the threshold level required to achieve the desired therapeutic response. This concentration must be maintained for a desired period. Subsequent administration of the drug must be timed appropriately to maintain this concentration at the target organ site. If too high a concentration is reached, safety may be compromised. If a subminimal concentration results, a period of non-therapy occurs.

A peak plasma concentration ($c_{\max}$) occurs at a time $t_{\max}$ after each administration of a drug product (Fig. 1). This concentration should be somewhat greater than the minimum effective plasma concentration needed to achieve the desired pharmacologic effect, but not so high as to cause side effects and toxicity. The minimum toxic concentration (MTC) is the concentration of drug in the blood that initiates an untoward response (toxicity, side effect). The *therapeutic index* is the ratio of the minimum toxic concentration of drug (MTC) in the blood to the minimum effective concentration (MEC) in the blood (MTC/MEC); the greater the number the safer the drug is.

Figure 1. Blood drug concentration – time curve in a pharmacologic or therapeutic response
The shaded area is the "area under the curve" (AUC).

The parameter $t_{\max}$ is important in developing a rational regimen for dosage form administration. The point at which the threshold concentration (i.e., the MEC) is reached is termed the *onset of activity*. The time from the onset to the point when the concentration falls below the threshold level is termed the *duration of activity*.

Bioavailability is best defined as the amount of an administered drug that reaches the general circulation and the rate at which this occurs. Attention must be given to bioavailability during the design of a new drug product because it may be adversely affected by the selection of excipients and unit manufacturing operations. The area under the curve (AUC) is the total area enclosed by the blood drug concentration – time curve. It represents the extent of bioavailability of an administered dose of drug.

Excess compression pressure in tabletting may, for example, result in tablets that pass intact through the gastrointestinal tract. The relationship of formulation design and manufacture to bioavailability is generally termed biopharmaceutics. Biopharmaceutic concerns are important when a new (generic) dosage form is being designed to be pharmacologically and pharmacokinetically equivalent (i.e., bioequivalent) to an already marketed product that is no longer protected by patent.

2. Routes of Administration [7]

Drug products are administered to the human body by different routes and in various physical forms such as solutions, emulsions, suspensions, ointments, creams, suppositories, powders, granules, capsules, and compressed tablets. The most important administration route for achieving systemic therapeutic effects is the *enteral route*; the unit is swallowed, the drug dissolves in the gastrointestinal fluid and is absorbed through the mucous membrane of the gastrointestinal tract into the general circulation. Other major routes include *rectal administration* for local medication of the mucous membranes or for a systemic effect after absorption through the mucous membrane of the colon.

Parenteral injection through the skin, utilizing a syringe and needle, requires strict attention to sterility during administration and in the preparation and packaging of the dosage forms and equipment.

3. Dermal application

is used for treatment of topical conditions (e.g., skin infections, psoriasis, acne, contact dermatitis). Drugs can, however, also be made available to the systemic circulation by percutaneous absorption.

Figure 2. The most important types of parenteral administration [10]

3.1. Parenteral Administration [8], [9]

Dosage forms for parenteral administration are designed for injection through the skin with syringes and needles of appropriate size and diameter. When small doses are involved the drug is supplied in single-dose glass ampules or multi-dose vials. The vials have rubber stoppers through which the needle of a syringe is inserted to withdraw the desired dose.

For large-volume administration in hospitals or clinic settings, the drug is delivered intravenously from glass flasks or pliable plastic containers hung near the patient. Metered pumps are often used to insure accurate dosing (number of drops per minute) over long periods. Portable systems are also available in which the patient "wears" a self-contained unit consisting of a metering device and drug supply.

Parenteral injections can deliver the drug directly to the general circulation intravenously (i.v.), subcutaneously (s.c.), or intramuscularly (i.m.), see Figure 2. The *intravenous route* can be used to administer a single dose (bolus) or for continuous administration over a long period (12 – 24 h). In the latter case, several drugs can be administerd in a sequential system ("piggybacked"). Hyperalimentation solutions containing carbohydrates, amino acids, vitamins, and other nutrients are large-volume parenteral dosage forms that are administered intravenously to sustain debilitated patients for long periods of time. These nutrient solutions are administered continuously through indwelling catheters.

Parenteral dosage forms are manufactured as sterile units. They must also be free of pyrogens and foreign particles. Parenteral administration has the major disadvantage of being a potential source of infection, irritation, or pain at the site of injection. It is the route of choice when a quick therapeutic response is needed (e.g., in emergency situations or with comatose patients). It is also useful when oral drug administration cannot be tolerated (i.e., with nausea or after gastrointestinal surgery). Some drugs can only reach the general circulation by parenteral injection, for example, because of chemical instability in the gastric fluid or because they cannot be absorbed via the gastrointestinal tract (e.g., insulin).

Oily solutions or suspensions may be administered by *subcutaneous or intramuscular injection* to create "depot" doses. The drug slowly leaches from the injection site to extend the period of therapy. Small, sterile, rodlike pellets can also be implanted beneath the skin to achieve therapy periods of several months. Such implantation requires lancing and local anesthesia.

Specialized parenteral routes include intraarterial, intrathecal, intraspinal, intradermal, and intracisternal administration. Intra-arterial injection may require surgery to reach the artery and is used to administer radioopaque contrast media for viewing a specific organ. An intrathecal injection involves direct injection into the cerebrospinal fluid. Intraspinal injections are administered into the dural membrane surrounding the spinal cord. Intradermal administration occurs when the drug solution is injected into the dermis and epidermis of the skin (e.g., with solutions used to test for allergies). Intracisternal injection involves introduction of the drug solution into one of the subarachnoid cisternae of the brain.

Peritoneal dialysis is an example of a specialized large-volume parenteral dosage form. Drug solutions are injected intraperitoneally to treat the membranes of the abdominal cavity.

3.2. Oral Administration [11]

The oral route is popular because of its convenience. Oral dosage forms do not require specialized equipment, are noninvasive, and are generally more economical to prepare and administer. The main type of oral drug administration is the swallowing of solid (e.g., capsules, tablets) or liquid (e.g., syrups, solutions, emulsions) dosage forms. The drugs either medicate the gastrointestinal tract itself (e.g., antacids, anthelmintics) or are absorbed through the gastrointestinal mucous membranes into the systemic circulation to achieve a therapeutic effect at a distant target site or organ.

Orally administered dosage forms can also be held under the tongue (sublingual) or in the cheek pouch (buccal). The drug is absorbed through the oral mucous membrane into the blood stream. It enters the jugular vein and passes directly to the heart, avoiding the liver on its first pass through the body. This is in contrast to absorption through the gastrointestinal tract where the absorbed drug first passes through the portal vein to the liver before distribution to the rest of the body. Thus, drugs that are metabolized quickly by the liver (first-pass effect) can be administered more effectively in sublingual dosage forms. Also, drugs needed to treat the heart (e.g., nitroglycerin for angina) are delivered rapidly to the site of action from sublingually administered solid dosage forms that dissolve quickly.

Some dosage forms are designed for local treatment of the mucous membrane and gums of the mouth and throat (i.e., mouthwashes, gargles, lozenges).

3.3. Dermal Administration

Certain dosage forms are designed to treat the skin and its appendages (the sebaceous and sweat glands). Therapy is localized and nonsystemic; percutaneous absorption of the drug should be avoided. Dermal dosage forms can contain greasy base ingredients (pastes, ointments) or can be emulsified semisolids (cold creams, vanishing creams). Some topical applications are delivered from pressurized aerosol containers as solutions, suspensions, emulsions, foams, or powders. Solution dosage forms (soaks) are also used as astringent applications to weeping wounds.

Recent developments in drug delivery systems include the transdermal route of drug administration for prolonged periods of therapy. The drug is present either in a reservoir of drug and excipient ingredients or in a drug – excipient matrix that are attached to adhesive backings ("patches") for application to the skin. The drug is then released from the unit and transferred through the skin to the systemic circulation (see also Section 7.2.2).

3.4. Rectal Administration

Drugs can be administered rectally as enemas (solutions or suspensions) or suppositories to treat localized conditions of the rectum or colon (cathartics, hemmorhoid treatment). Such dosage forms can also be used for systemic therapy if the drug is absorbed through the mucous membrane of the colon. Treatment of comatose patients is possible by such rectal administration. This route is also useful in the treatment of infants, debilitated elderly patients, nauseated patients, and those having undergone recent gastrointestinal surgery. For example, debilitated cancer patients can gain relief from pain after administration of suppositories containing narcotic drugs.

3.5. Other Routes of Administration

Ophthalmic, Nasal, and Otic Routes. Various ophthalmic conditions (e.g., glaucoma) can be treated by local application of sterile, isotonic solutions or suspensions delivered from appropriate containers (glass dropper or plastic squeeze bottles). Sterile ophthalmic ointments are applied under the lower eye lid from specially designed tubes; any powdered drug present in an ophthalmic ointment or suspension must be of a very fine particle size ($\leq 10\,\mu m$) to avoid irritation.

Nasal solutions, drops, or sprays from appropriately designed plastic containers are used to treat local conditions of the nasal mucosa (e.g., vasoconstrictor drugs to alleviate "stuffy nose" and anti-inflammatory agents to treat perennial rhinitis). Pressurized aerosols can also be used to treat nasal conditions.

Transnasal drug delivery via absorption through the nasal mucosa has gained strong interest for systematic therapy [12]. Absorption of polypeptides by this route is the subject of considerable research. It may be an alternative route of administration of insulin for diabetic patients. The assurance of accurate dosing is, however, still a problem.

Otic (aural) administration of drug products is used only for local treatment of the external auditory canal. Since this canal is lined with dermal tissue and not mucous membrane, infections are treated much like skin infections.

Intravaginal Administration. Dosage forms applied vaginally are intended for treatment of local infections. Solutions (douches), aerosol foams, creams, or suppositories are used. Spermicidal agents can be administered similarly. Intrauterine devices that release small amounts of contraceptive drugs for long periods of time are recent developments [13]. One such commercially available product (Progestasert, ALZA) acts as a progesterone reservoir that releases effective amounts of the drug for up to one year. Effects are local, thus minimizing the systemic side effects that accompany oral administration.

Oral Inhalation [14]. Pressurized aerosol drug products are available for inhalation and are used with adapters that are placed between the upper and lower teeth during actuation. Such solution or suspension products are intended for local pulmonary use (e.g., asthma attacks) or for systemic therapy. Rather complex technologies are required to ensure delivery of accurate doses (metered valves) and to control the particle size of the delivered products. Inhalation aerosols are also available for sublingual medication. Nitroglycerin, for example, can be delivered in metered doses directly under the tongue from pressurized aerosol containers for quick absorption and therapy of angina pain.

4. Types of Dosage Forms [15]

Dosage forms can be classed according to their use or physical form. In the former case the classes correspond to the routes of administration (Chap. 2): topical or external use (creams, ointments, pastes); oral use dosage forms (syrups, tablets, capsules); rectal suppositories; parenteral injections; transdermal patches; and localized drops (ocular, nasal, otic). In the present chapter, currently used dosage forms are classified according to their physical form as follows:

1) Liquid solutions
2) Liquid dispersions
3) Semisolid dispersions
4) Plastic dispersions
5) Solid dosage forms including coated solids
6) Prolonged action products
7) Pressurized aerosols
8) Nonpressurized gaseous dosage forms (inhalants)
9) Radiopharmaceuticals

4.1. Liquid Solution Dosage Forms [16]

Liquid solutions can be used for various pharmaceutical purposes:

1) As oral medication: sweetened, flavored, with aqueous or hydroalcoholic (water – ethanol) solvent system
2) For external application (soaks, baths) to skin wounds
3) Application to body cavities or apertures: enemas, douches, bladder irrigations
4) As inhalations, by mouth, from atomizers, nebulizers, and pressurized aerosols
5) As gargles or mouthwashes to treat the mucous membranes of the mouth and throat
6) As eye, ear, or nasal drops for local application
7) Parenteral injection

4.1.1. Solutions

Early compendia identified solutions as liquid preparations of one or more substances dissolved in liquid solvents, which by reason of their ingredients or method of preparation could not be classified in some other group of official dosage forms. They were termed “liquors” and were generally made by simple dissolution or by chemical reaction.

Official requirements for pharmaceuticals and their dosage forms are specified in national

and international pharmacopeias. The Pharmacopea Internationalis and the European Pharmacopoeia are international works. National pharmacopeias include the British Pharmacopoeia, the Deutsches Arzneibuch (DAB 7, 1987), and the United States Pharmacopeia (U.S.P. XXII, 1990). In this article specifications are illustrated with examples from the U.S.P.

The United States Pharmacopeia and National Formulary (U.S.P./N.F.) currently identifies solutions according to their intended use (e.g., oral solutions, ophthalmic solutions, and inhalation solutions). Sterile parenteral solutions are termed injections.

4.1.2. Extractive Solutions

Several types of drug solution dosage forms that were originally developed years ago by extraction of plant (crude drug) materials with various solvents (menstrua) are still identified in compendia. Thus, various syrups, spirits, tinctures, and fluid extracts are extractive solutions that are listed in U.S.P. XXII and N.F. XVII. Some of these contain therapeutic ingredients (e.g., Ipecac Syrup, Senna Fluid Extract, Cascara Sagrada Fluid Extract, and Belladonna Tincture). Extracts that do not contain therapeutic ingredients were developed as flavored diluting vehicles for compounding admixture prescriptions (e.g., Peppermint Spirit, Vanilla Tincture, Tolu Balsam Tincture, and Tolu Balsam Syrup in N.F. XVII). Aromatic waters also belong to this type of solution. The last official waters in the U.S.P./N.F. are Peppermint Water, Rose Water, and Orange Flower Water.

Syrups. Aqueous solutions containing high concentrations of sucrose or other sugars are termed syrups. U.S.P. XXII lists the item "Syrup" as a near-saturated solution of sucrose in purified water. Certain polyols (e.g., glycerol, sorbitol) and flavoring agents can be added. Some syrups can be made by extraction; some are nonmedicated flavoring agents.

Aromatic waters are clear, saturated aqueous solutions of volatile oils or aromatic solids. They were used in the 1930s and 1940s as flavoring vehicles and had a minor carminative effect.

Elixirs. Sweetened, hydroalcoholic solutions for oral use are termed elixirs. Some are medicated; others were developed as official flavoring vehicles. Iso-alcoholic Elixir is an example. When this elixir was official it appeared in a high-alcoholic (75 vol%) and a low-alcoholic (10 vol%) form. By mixing proportions of each, a pharmacist could obtain varying percentages (10 – 75 vol%) of ethanol to insure solubility of prescribed drug entities in the extemporaneous compounding of prescriptions.

In commercial use the term "elixir" (unless followed by "U.S.P." or "N.F." in the United States) does not imply the official form. This is also true of terms such as "syrup" and "tincture".

Spirits and essences were alcoholic or hydroalcoholic solutions of volatile substances. Some were medicated, while others were flavoring vehicles to ensure a high ethanol content.

Tinctures were developed as alcoholic or hydroalcoholic solutions of plant drugs, synthetic drugs, or flavoring ingredients. Orginally, tinctures existed in three general types:

1) *Potent tinctures*: 100 mL contained the active ingredient content of 10 g of crude dried drugs (belladonna tincture)
2) *Nonpotent tinctures*: 100 mL contained the active ingredient content of 20 g of crude dried drug
3) *Flavoring tinctures*: 100 mL could contain the flavor principles of up to 50 g of crude, dried vegetable or fruit powder (sweet orange peel tincture, lemon tincture)

Fluid Extracts. Fluid extracts of plant materials were high in ethanol and could be viewed as standardized tinctures. They were designed so that each milliliter contained the extracted principle of 1 g of crude, dried drug.

4.1.3. Parenteral Solutions (Injections) [17]

Parenteral solutions are meant for injection through the skin and must be sterile, pyrogen-free, and isotonic. Their pH must be close to that of blood.

4.1.4. Inhalations

Inhalations are aqueous solutions for treatment of the lower respiratory tract. The smaller the droplet size delivered, the deeper into the respiratory tract the medication will reach. Administration necessitates use of inhalation devices, with nebulizers delivering smaller droplets than atomizers. Pressurized aerosols with mouthpiece adapters and actuators can deliver fine mists by means of specially designed valves. Such valves can deliver metered doses, this is an advantage over nebulizers and atomizers.

4.1.5. Ophthalmic and Nasal Solutions (Drops)

Ophthalmic and nasal solutions are used for local medication. Both should be isotonic and ophthalmic solutions must be sterile.

4.1.6. Otic Solutions

For application to the ear canal, otic solutions are best prepared with nonaqueous solvents. Anhydrous glycerol is a popular solvent.

4.1.7. Liniments

Liniments are liquid preparations meant for topical application with rubbing. They may be hydroalcoholic solutions, oily solutions, suspensions, or emulsions.

4.1.8. Enemas and Douches

Enemas and douches are solutions used to treat local rectal conditions or as vaginal medication, respectively.

4.1.9. Mouthwashes and Gargles

Mouthwashes and gargles generally are aqueous or hydroalcoholic solutions of aromatic principles and/or antiseptics. They are used to treat conditions of the mouth and throat or to refresh the buccal cavity. Antiseptic effects are, however, rather transient.

4.1.10. Collodions

Collodions are polymeric solutions (pyroxylin) that utilize diethyl ether and acetone as solvents. These viscous liquids are applied to the skin with applicator bottles. Evaporation of the solvent(s) leaves a protective film on the skin. Plasticizers can be added to provide a more flexible film. Drugs can also be added (e.g., salicylic acid as a keratolytic agent to treat corns and warts).

4.2. Liquid Dispersions [15], [16], [18] , [19]

Liquid dispersions include suspensions of solids in liquids. Such suspensions can be formulated as oral products to reduce the bad taste of a drug or to control chemical degradation of the drug. When applied topically they generally are termed lotions.

This group also includes pourable oil-inwater (o/w) or water-in-oil (w/o) emulsions. Emulsification, like suspension, can be used to overcome bad taste or chemical degradation. Oral emulsions are o/w, whereas external-use emulsions (also called lotions) can be o/w (the vanishing type) or w/o (the cleansing or "cold cream" type). Suspensions and emulsions can be packaged for use as aerosol products.

4.3. Semisolid Dosage Forms [15], [18]

Dosage forms that are semisolids at room temperature include mucilages, gels (jellies), magmas, ointments, creams, and pastes.

Gels, Magmas, and Mucilages. This group of semisolids consists of colloidal particles dispersed in a liquid medium. They can be thixotropic systems that are semisolid upon standing but become liquid with shaking or stirring. Gels (jellies) are systems that contain either organic polymers (e.g., methyl cellulose, alginates) with entrapped liquid or inorganic particles (e.g., aluminum hydroxide) suspended in a liquid. The liquid phase of gels is generally water, but it may also be an oil. Mineral oil, for example, can form a gel structure with polyethylene for use as a topically applied base.

If the dispersed macromolecules are distributed throughout the liquid without specific boundaries or without a network between them and the liquid, the system is considered single phase. If the gel consists of larger aggregates of dispersed particles, it is considered a two-phase system and termed a magma (bentonite magma).

Single-phase gels can consist of synthetic organic molecules (carbamer or carboxypolymethylene, a carboxyvinyl polymer) or may be dispersions of natural gums (acacia, tragacanth). Such gum dispersions can be termed mucilages.

Gels can be applied topically as in tretonoin gel (U.S.P.), an acne treatment. Sodium fluoride and phosphoric acid gel (U.S.P.) is used as a dental application. Gels and magmas can be used orally; aluminum hydroxide gel and magnesia magma (U.S.P.) are antacid preparations. Some mucilages can be used as pharmaceutical adjuvants to increase the viscosity of preparations or to adjust mouthfeel.

Ointments, Creams, and Pastes. These types of dosage forms are designed for application to the skin. However, ophthalmic ointments are applied under the lower eyelids from specially designed tubes; they must be sterile and should not contain gritty powders.

Ointment bases can be classified in the following manner:

1) *Oleoginous, hydrocarbon bases* have a greasy consistency, cannot contain significant amount of admixed water, and are occlusive to the skin, i.e., they restrict water evaporation from the skin surface
2) *Absorptive bases* are either semisolid mixtures that form w/o emulsions upon sorption of water (Hydrophilic Petrolatum, U.S.P. XXII) or w/o emulsions that can take up more water (Cold Cream, U.S.P. XXI)
3) *Water-removable bases* are o/w emulsions (Hydrophilic Ointment, U.S.P. XXII; Vanishing Creams) that are water-washable and less occlusive than absorptive bases or oleoginous bases (water-washable denotes bases that are insoluble in water but are o/w emulsions and can therefore be washed off with water)
4) *Water-soluble bases* that are termed greaseless ointments are least occlusive, they are blends of poly(ethylene glycols) (Polyethylene Glycol Ointment, U.S.P. XXII)

The choice of an ointment base depends upon the condition being treated, the degree of desired occlusiveness, and the stability of the drug to be incorporated. Ophthalmic ointments are generally nonemulsified.

Pastes are semisolids that contain powders. Their base ingredients can be gels or oleoginous mixtures. Pastes can thus absorb more water than greasy ointments and can be used to absorb serous secretion in lesion oozing.

The term *cream* denotes an emulsified semisolid such as cold cream (w/o) and vanishing cream formulations (o/w). As dermal applications, they have more cosmetic appeal to users than greasy ointment bases. Creams can also be used to medicate body cavities (rectum, vagina). They can be delivered from pressurized aerosol containers.

4.4. Plastic Dosage Forms (Suppositories) [15], [20]

Suppositories are semirigid, plastic dosage forms designed for insertion into body cavities (rectum, vagina, or urethra). They can be used for systemic therapy (rectally) or for localized treatment.

Rectal suppositories are the route of choice for comatose patients or after gastrointestinal surgery. They also find use in pediatric and geriatric medication.

Depending upon the base used, suppositories either melt at body temperature upon insertion (cocoa butter) or dissolve in the cavity (poly(ethylene glycol) blends, glycerinated gelatin). Glycerinated gelatin base suppositories have a rubbery consistency (70 % glycerol, 20 % gelatin, 10 % water plus drug).

Glycerin Suppositories (U.S.P. XXII) have a unique base: glycerin that is gelled or solidified with sodium stearate.

Suppositories based on cocoa butter can be prepared manually by pharmacists. However, heating mixtures of such base and drug, followed by pouring into calibrated molds and chilling, is the preferred method of preparation.

Poly(ethylene glycol) and glycerinated gelatin base suppositories must be made by fusion and molding. On a large industrial scale, all

suppositories are made by heating and molding procedures.

4.5. Solid Dosage Forms [15], [21], [22]

Solid dosage forms have progressed from powder blends dispensed as bulk powders for administration by teaspoonful dosages in water or in measured amounts wrapped in folded paper squares (folded powders, chartulae) to modern compressed tablets. Pharmacists have also dispensed cachets, capsules, tablet triturates, granules, troches, and pills as solid dosage forms.

Bulk Powders and Effervescent Powders. Bulk powders are blends of drug and water-soluble diluents for dissolution in water. The resulting solution can be administered orally or applied externally. Dosing of such powder mixtures by teaspoonful measurement affords poor accuracy and precision. Small-dose, potent drugs should therefore be weighed accurately as a dose and enclosed in a folded paper. Alternately they can be dispensed in "zip-lock" plastic envelopes/bags or encapsulated in gelatin capsules.

Bulk powders can be formulated with ingredients that effervesce on addition of water (e.g., sodium bicarbonate plus blends of citric and tartaric acid). Such powders provide carbonated, aqueous solutions to help mask bad-tasting drugs. Flavoring and sweetening agents can also be added to the powder blend.

Dusting Powders. Dusting powders are applied externally to treat skin lesions or rashes; they should have an impalpable particle size (100 – 150 μm). They are sprinkled onto the affected skin from sifter-top containers. They generally contain absorbent substances (starch, kaolin) to absorb serous fluid and talc or metallic stearates as skin lubricants.

Insufflations are obsolete. They were powder blends of fine particle size that were propelled from atomizer-like devices (insufflators) into body cavities.

Lyophilized Powders. Several drug products exist as lyophilized (freeze-dried) powders for reconstitution into solutions or syrups by the pharmacist or patient. This dosage form is generally used when the drug would otherwise decompose in the presence of the solvent system during warehousing and distribution. The reconstituted product should be used in a relatively short period of time and should be refrigerated by the patient. An example of such a product is an antibiotic syrup for pediatric use. Parenteral dosage forms can also exist as lyophilized powders to which sterile solvents must be added under sterile conditions directly before use.

Capsules and Cachets. Cachets are mentioned here only for historical reasons. They were used before gelatin capsule shells became available. They consisted of two thin disks usually made of rice flour. Each disk had a raised edge creating a hollow area. Powder was placed in one of the disks, its edges were then carefully wetted, and the second disk was placed on top of it. On drying, a sealed edge was formed. Cachets, also called Konseals, were designed to hold ca. 0.5 – 1.0 g of powder. They were intended to be swallowed with water.

Gelatin capsules may be either hard or soft (→ Gelatin, Chap. 4.3.) and are utilized to deliver small volumes of powder orally. The formulations of gelatin capsules do not require binders or disintegrating agents and are less complicated to formulate than compressed tablets. During the manufacture of the gelatin shells coloring agents, opaque pigments, and flavors can be added to the gelatin mixtures. Upon swallowing, the capsule's shell dissolves relatively quickly (< 10 min), making the enclosed powders available for gastrointestinal dissolution. Thus, bioavailability should be more complete and faster than that of compressed tablets.

Hard gelatin capsules are made from water and gelatin and can be produced in several sizes. They are of two-part construction (cap and base) and can be filled and dispensed by pharmacists extemporaneously or mass-produced. When the capsules are filled by high-speed machines, lubricants (metallic stearates, talc) can be added to the formulations to ensure uniform powder flow from the filling hoppers to each capsule shell. Such capsules range in size from number 000 to 5. The latter can hold ca. 65 mg of aspirin powder; number 00 can hold ca. 650 mg.

Soft gelatin capsules contain glycerol, as well as water and gelatin [23]. They cannot be filled

extemporaneously because they have to be made by a heat-sealing process (Fig. 3). Two rolled sheets of gelatin are kept pliable with mild heat (37 – 40 °C). The rolled sheets meet in an injection portion of the machine where the ingredient is injected into the resulting capsular form. This is sealed and ejected as a finished capsule. Excess gelatin is reprocessed. The encapsulated ingredients can be a powder, semisolid, or nonaqueous drug solution. Soft gelatin capsules can take any form from a globule (pearl) to the traditional capsular shape.

Pills. Although compressed tablet dosage forms are often called pills, this is a misnomer since pills were at one time a popular solid dosage form in themselves. Pills were an attempt to deliver a unit dose of a drug in a convenient, portable solid form. Their preparation entailed addition of adhesive liquids (e.g., syrup or gum mucilages) to medicated powder blends. Upon suitable manipulation the powders then became a pliable mass that was rolled into pencil-like cylinders called pipes. The pipes were each divided into an appropriate number of units on a gauged pill tile. Each unit was then rolled into a sphere, dried, and dusted with powder to minimize stickiness. Although attempts were made to add ingredients that would swell when exposed to gastrointestinal fluids to aid disintegration of such pills upon swallowing, bioavailability of the drug was poor. Solid dosage forms in pill shape are now made by granulation and compression (i.e., as a compressed tablet).

Tablet Triturates and Hypodermic Tablets. Tablet triturates were originally small, round tablets made in a small, hard, rubber mold that accomodated 50 – 100 tablets. They were intended to deliver a potent drug in an accurate amount that dissolved quickly and completely. They were composed of the drug, lactose, and/or sucrose. Binding of the ingredients was achieved by adding small amounts of 50 % ethanol to the drug – sugar blend before manual compaction into the mold.

Hypodermic tablets were similar products, intended for use by hypodermic injection after dissolution in sterile water. Today such products can be made with tablet compression equipment. One of the few such products used today is Nitroglycerin Tablets (U.S.P. XXII) for sublingual use to achieve quick relief of chest pain in angina patients. These tablets are very friable and crumble easily during handling and transport.

Troches and Lozenges are small solid disks or cubes that are designed to dissolve slowly in the mouth without disintegration to provide medication to the mucous membranes of the mouth and throat. Originally an adhesive kneadable mass was prepared, rolled into a sheet, cut into appropriate size and shape, and dried. Today such dosage forms are made by granulation (without disintegrating agents) and compression. Crystalline candy bases can also be formulated to which drug solutions can be added. Such syrup bases can then be molded into appropriate dosage units.

Granules are powder blends that have been either lyophilized or massed. Massing (wet granulation) involves addition of an adhesive binding solution (e.g., gelatin or polymer dispersion, gum, starch paste) to the powder blend. The mixture is then passed mechanically through appropriate sieves to obtain granules of the required size.

Granules can be used as such (in teaspoonful or tablespoonful doses) in water. Effervescent

ingredients (see page 10) can also be included in granule formulations to add flavoring and carbonation to the medicated solution.

Granules prepared by massing can be used to prepare compressed tablets by the wet granulation method (see page 12). The granules are dried, resieved, and blended with glidant and ejection lubricating powders (talc, metallic stearates) prior to compression.

Compressed Tablets. The compressed tablet is the most popular dosage form. It offers convenience, ease of administration, stability, accurate and precise dosing, and good bioavailability. Once the formulation has been developed and proved clinically efficacious and safe, production validation and specifications can be developed to ensure batch-to-batch reliability. Millions of tablets can be produced daily, insuring economical preparation.

Appropriate quality control procedures during tablet manufacture and of the final product assure tablet-to-tablet consistency and reliability. Such tests include weight uniformity, content identity and uniformity, tablet hardness, disintegration time, and friability. Each manufacturer establishes an appropriate set of tests with specification limits. Bioavailability is determined during clinical testing. During preformulation studies, the properties of the drug are investigated to insure stability, safety, and therapeutic effectiveness.

Tableting Procedures and Equipment. Tableting may be performed by direct compression of powder blends or by preparation of suitable granulations followed by compression.

Direct compression involves the admixture of the necessary powders followed by compression with tablet compression presses. Powder blends of small particles must have acceptable flowability and compressibility properties. This is not always the case. Modern equipment is, however, more adaptable to direct compression than in the past because mechanical delivery to the dies has been improved. Excipient ingredients (diluents, binders, disintegrating agents) are now available in granular form to insure better flow and compressibility.

A granulation blend of 90 – 95 % granules (ca. 10 – 40 mesh, 2 mm – 425 µm) plus 5 – 10 % fine particles generally provides better compressibility and flowability than fine powder blends.

When direct compression is not possible, wet or dry granulation (slugging) can be used. Granulation is required when the powdered drug with diluent etc. does not possess sufficient compressiblity calling for addition of a binding solution and granulation. Granulation is also advisable, if the powder blend does not flow well to ensure uniform content and weight of the tablets.

Wet granulation is widely used for tablets when the active ingredient is stable to water and heat. *Dry granulation (slugging)* is used when the drug is not stable to the conditions of wet granulation and the ingredients cannot be directly compressed. The ingredients are blended and compressed on a heavy-duty tablet press or slugger. Large hard tablets are produced, these "slugs" are 28 – 50 cm in diameter and weigh ca. 25 – 30 g. The slugs are then ground and sieved to appropriate mesh size and recompressed.

Various *excipient ingredients* are used in tablet production:

1) Diluents to insure appropriate size and convenient volume (e.g., lactose, calcium phosphate)
2) Disintegrating agents to aid tablet disintegration and dissolution of active ingredients (e.g., starch, microcrystalline cellulose)
3) Lubricating agents and glidants to ensure flowability of granulation, as well as antiadherents to ensure release from dies and punch faces (e.g., magnesium stearate, talc)
4) Binders to increase powder adhesion and ensure appropriate granule formation and compression (e.g., gelatin starch paste, methyl cellulose)

The major components of a *tablet press* are as follows (Fig. 4):

1) The *dies* are the units to which the granulation is delivered and whose shape determines the shape of the tablet
2) The *upper punch* fits snugly in the die and delivers the pressure
3) The *lower punch* also fits snugly in the die, it controls the volume of granulation delivered to the die and therefore tablet weight

The compression cycle (Fig. 5) begins with the delivery of the granulation from the hopper to the die by a feeder device that allows uniform

Figure 4. Tableting tools (courtesy of Fette GmbH, Hamburg, Germany)
a) Upper punch; b) Die; c) Lower punch

filling. The lower punch is at its lowest position at this point. The upper punch is then lowered to deliver a defined pressure. It then moves upward together with the lower punch to eject the tablet. Single punch presses have only one die – punch unit and compression is fast. On a multistation rotary press (one station consists of one die, one upper punch, and one lower punch), more than 60 dies can be assembled in a rotating circular table (Fig. 6). The punches ride over and under the dies in well-tooled cam tracks or channels in the head and foot areas of the press to achieve the synchronized upward and downward stroking action.

Newer high-speed presses can produce $>10\,000$ tablets per minute. Such units are equipped to measure compression and ejection forces and monitor tablet weight. Weight variations can be adjusted automatically by computer program. Feeding of granulation in sufficient quantity and rate to the die can be a problem. Standard gravity feed from hopper to feeder frame is not sufficient. Rotary agitator mechanisms within the feeder-frame units are used to induce faster feeding to the dies.

Types of Compressed Tablets. Compressed tablets can be divided into three main groups (Fig. 7):

1) Single-layer, uncoated tablets
2) Layered tablets
3) Coated tablets

Single-layer, uncoated tablets may be classified as follows:

Figure 5. Compression on a single-punch tableting press (courtesy of Vector Corp., Marion, Iowa)
a) Upper punch; b) Granulation in die cavity; c) Feed shoe; d) Die; e) Lower punch
The feed shoe is filled with granulated materials from a hopper and is positioned over the die cavity (A) which then fills (B). The feed shoe retracts (C) and the upper punch lowers to compress the material (D). The upper punch retracts and the lower punch rises to eject the compact (E).

1) Tablets to be swallowed for systemic use or to medicate the gastrointestinal tract
2) Tablets that are to be chewed before swallowing; these are popular with young children (vitamins) and are generally flavored and sweetened
3) Buccal or sublingual tablets for quick dissolution and absorption and used for drugs that are not stable in gastrointestinal fluid, that are needed for quick cardiac therapy (angina), or have significant first-pass liver metabolism (see page 6)
4) Effervescent tablets
5) Lozenges or troches
6) Vaginal inserts
7) Pellets for parenteral implantation

Layered tablets may contain two or more layers and are prepared on special presses in which two or more different granulations are delivered from several hoppers. Layered tablets are used for two main reasons:

1) To separate ingredients that may be chemically or physically incompatible during processing and storage
2) To provide an initial (loading) dose from one layer and a prolonged-release dose from another; a nonmedicated layer (e.g., lactose granulation) can be used to separate the drug-containing layers

In *coated tablets* the coating protects the ingredients from atmospheric oxygen, water, carbon dioxide, and/or light [24]. Tablets are also coated to mask bad taste and to control the site of disintegration and drug dissolution. In the case of enteric coatings, for example, the tablet remains intact in the stomach but disintegrates with drug dissolution in the duodenum. Powders, granules, and tablets are also coated to control the rate of drug release.

Sugar coatings are applied in rotating pans. The core tablets are somewhat harder and more spherical than tablets that are not to be coated so that they can withstand tumbling and thus facilitate application of the coating. Batches of core tablets are initially dusted to remove powder from their surface and are sealed with a thin coat of food-grade shellac. Alternate coatings of syrup and powdered sugar are then added with intermediate drying until a rounded geometry is obtained. Smoothing coats of syrup are applied with coloring agents, if called for. Finally, the tablet is polished with a thin coating of wax and imprinted with a logo.

Film coating is faster than sugar coating and allows tablet surface engravings to be

seen. Unlike sugar coating it does not increase tablet weight significantly. Polymeric solutions (e.g., cellulose acetate phthalate for enteric coatings, sodium carboxymethyl cellulose for water-soluble coatings) are sprayed onto the tablets as they tumble in rotating pans (Fig. 8). Such solutions can contain plasticizers (e.g., poly(ethylene glycols), phthalates), coloring agents, and opaquing ingredients. Originally, organic solvents were used (e.g., acetone, chloroform). Modern technology now allows the use of aqueous polymeric dispersions. The polymers can be used to produce enteric film coatings, as well as coatings that dissolve in gastric fluids.

Film and sugar can be accomplished in equipment other than rotating pans. Air-suspension coating (Wurster apparatus) employs a cylindrical chamber in which the cores are suspended in a stream of air (→ Microencapsulation, Chap. 4.5.). Coating solutions are injected into this air stream with quick solvent evaporation. This technique can also be used to coat powders or beads. The coated beads or powders are then encapsulated or compressed into tablets to provide prolonged-release dosage forms (see page 30).

In *pressure coating*, coatings are compressed around core tablets. Two tablet presses are used in tandem: one to make the core tablet and the other to receive the core and compress the coating around it. The coating can be a protective one. However, it can include the initial-release portion of a prolonged-action tablet, with the core being a sustained-release unit. This situa-

tion also can be accomplished with sugar coating technology: the initially released drug portion added in the sugar coating and the sustained-release portion in the core.

Figure 7. Compressed tablet types

4.6. Prolonged-Action Dosage Forms [26–29]

The purpose of prolonged-action dosage forms is to extend periods of therapy from a single administration to two or three times those produced by conventional dosage forms. This can be accomplished by using orally administered dosage forms that release a portion of their drug content relatively quickly to induce onset of the therapeutic response and thereafter release the remaining drug content at a rate that approximates the rate of elimination of the drug from the body (Section 7.2.1). Prolonged therapy can also be achieved by transdermal drug systems [30], [31], ocular [32] and intrauterine [33] inserts, and parenteral dosage forms [34] (Section 7.2.2).

4.7. Pressurized Aerosol Dosage Forms [19]

Aerosols are dispersions of liquid droplets or small solid particles in gases. Gaseous dispersions can be produced from atomizers, nebulizers, or insufflators. Pressurized containers utilizing various propellant gases for delivering drug products through appropriately designed valve systems and actuator devices have been available since the 1950s (see also Chap. 6). These propellants include liquefied gases or gas mixtures. Examples are the Freon series of fluorinated hydrocarbons (e.g., Freon 12, CCl_2F_2) and hydrocarbons (e.g., butane, propane). Nonliquefied compressed gases are also used (e.g., carbon dioxide, nitrogen monoxide, dinitrogen monoxide). Medications can be produced in the form of suspensions, emulsions, pastes, gels, solutions, and foams depending on the formulation, valve system, dip-tube, propellant, actuator, and container. They can be used in inhalation therapy, for external application, in dental care, for vaginal therapy, and for cosmetic and toiletry products (e.g., antiperspirants and shaving foams).

4.8. Nonpressurized Gaseous Dosage Forms (Inhalants) [35]

Some drugs have low vapor pressures at room temperature and atmospheric pressure (e.g., propylhexedrine and amyl nitrite). Inhalants are prepared by impregnating suitable inert (fibrous) materials with such drugs. Cylindrical rolls of the impregnated material are then fabricated into a size that can fit into a rigid plastic tube (inhaler), for use by gentle insertion of the inhaler tip into the nostrils and sniffing (e.g., Propylhexedrine Inhalant and Amyl Nitrite Inhalant, U.S.P. XXII). The gaseous drug then medicates the nasal membranes. Aromatic ingredients can be added.

4.9. Radiopharmaceutical Dosage Forms [36]

A radiopharmaceutical is a chemical or drug that contains a radioactive isotope for human use in diagnosing or treating a disease state. These specialized drugs are dispensed as traditional dosage forms. For example, cyanocobalamin ^{57}Co capsules are used as diagnostic aids for pernicious anemia; sodium ^{131}I iodohippurate injection is used for diagnosis of renal function conditions and sodium ^{32}P phosphate solution in diagnosis and localization of ocular tumors. See also → Diagnostic Reagents, Chap. 6.

5. Pharmaceutical Excipients [37], [38]

Excipient ingredients, also called adjuvants or pharmaceutical necessities, are nontherapeutic ingredients that expedite the manufacture of dosage forms, make the delivery of the active ingredient possible, and/or ensure appropriate bioavailability (see page 3). For example, compressed tablets containing very small doses of drugs (<10 mg) also contain glidant/lubricant excipients (talc, starch) to aid the uniform delivery of the granulation from hopper to die for accurate dosing and tablet weight. Lactose, as a diluent, gives the needed bulk to such formulations. Gelatin can provide necessary adhesion as a binder agent, and a disintegrating agent (microcellulose) speeds up the rates of dissolution and gastrointestinal absorption of the drug.

Excipients should be pure, nontherapeutic, chemically stable, nonreactive with the drug, atmospheric oxygen, and/or water vapor, nonallergenic, odorless with an acceptable color and taste, and inexpensive. The physical nature of the excipient varies with the dosage forms and its physical state: liquid, semisolid, rigid but plastic (suppositories), and solid.

Solvents and Cosolvents. Purified Water (U.S.P./N.F.) is suitable for general use in oral and dermal drug products. Several U.S.P. types of water are used with parenteral dosage forms (Water for Injection, Bacteriostatic Water for Injection and Sterile Water for Injection, U.S.P./N.F).

Several water-miscible solvents are used in liquid dosage forms: ethanol (both pure and denatured), glycols, polyhydric alcohols (glycerol, sorbitol), and acetone.

A number of water-immiscible solvents are also employed: vegetable oils (peanut, soybean, cottonseed oils), mineral oil. Diethyl ether is used to solubilize pyroxylin for thickening in collodions.

Stabilizers. Several types of stabilizer are utilized to guarantee the required shelf-life: antioxidants (e.g., sodium sulfite), antimicrobial preservatives (e.g., parabens), and buffers (e.g., acetate – acetic acid, Sorensen phosphate solutions).

Excipients of Palatability [39]. Such ingredients assure product elegance and better patient compliance. They include colorants, flavors, sweeteners, and perfumes. Such ingredients must not harm product stability nor the patient (allergy, primary irritation).

Colorants include water-soluble and oil-soluble, coal-tar-derivative dyes. In the United States dyes are certified (or decertified) by the FDA. Colorants from natural sources include carmine from insects and caramel. Lakes are certified aluminum or calcium salts of coal-tar (aniline) dyes, that are water- and oil-insoluble. They are used in solid dosage forms. Pigment colorants [e.g., white titanium dioxide; red, yellow, and brown iron(III) oxide] f ind wide use in cosmetic formulas (e.g., face makeup).

Flavors can be complex mixtures of synthetic organic compounds formulated by specialty companies. They can also be of natural origin (e.g., peppermint, vanilla, glycyrrhiza, and anise). The U.S.P./N.F. still lists certain nonmedicated products (syrups, elixirs, fluid extracts, tinctures, aromatic waters, and spirits) as official entities, for use as flavored diluting solutions (e.g., Tola Balam Syrup, Aromatic Elixir, Peppermint Water, and Peppermint Spirit); see also Section 3.1.2.

Sweeteners may be sugars but several polyhydric alcohols also have a sweet taste (glycerol and sorbitol). Saccharin and aspartame are nonsugar sweetening agents that are used in preparations for diabetic patients.

Natural *perfume ingredients* and blends of synthetic aromatic compounds can be considered as excipients in cosmetic products. However, most dermal dosage forms omit such compounds to reduce the risk of irritation and allergic reactions.

Surfactants. Various surfactants (anionic, cationic, nonionic, and amphoteric) are used in several types of cosmetics and dosage forms [40]:

Anionic surfactants

1) Soaps: sodium oleate, potassium stearate, trolamine laurate
2) Fatty alcohol sulfates: sodium lauryl sulfate
3) Alkyl aryl sulfonates: sodium dioctyl sulfosuccinate

Cationic surfactants

Quaternary ammonium salts: benzalkonium chloride, c etyltrimethylammonium bromide, cetylpyridinium chloride

Amphoteric surfactants

1) Natural: lecithin
2) Synthetic: dodecyl-β-alanine, *N*-dodecyl-*N*,*N*-dimethylglycine, *N*-alkyl-β-aminopropionate

Nonionic surfactants

1) Sorbitan esters: sorbitan trioleate
2) Glycerin esters: glycerylmonostearate
3) Poly(ethylene glycol) esters: polyoxyethylene 50 stearate
4) Polyoxyethylene ethers: polyoxyethylated lauryl ether, polyoxyethylated octyl phenol
5) Polyoxyethylene – polyoxypropylene block copolymers: polaxamers
6) Polyoxyethylated sorbitan ester: polysorbate 80

They serve as primary emulsifying agents (both o/w and w/o), wetting agents, and solubilizing agents (micellar solubilization). Thus, they are used in liquid (lotions) and semisolid (creams) emulsions, liniments, suspensions, mouthwashes, and solid dosage forms. Less than critical micellar concentrations aid in the dissolution of poorly water-soluble drugs from solid dosage forms in the gastrointestinal tract, thereby increasing the bioavailability of the drug. Cationic agents are seldom used as emulsifiers or wetting agents but are widely employed as antimicrobial preservatives. The synthetic amphoteric surfactants are generally expensive and are used mainly in cosmetic formulations.

Polymers can increase the viscosity of emulsions and suspensions, thereby increasing stability while delivering a more palatable or luxurious-feeling product.

Other polymers are used in solution to coat powders, granules, or compressed tablets; to alter the site of dissolution (in the small intestine rather than in the stomach); to slow the release of the drug for prolonged periods of therapy; or to increase product stability against environmental chemicals or other drugs that are present in the dosage form. An example of the latter would be the presence of two drugs in a tablet or capsule formulation which, when intimately mixed, would form a eutectic at room temperature. Polymeric coating of the powdered particles of one of the drugs prevents intimate contact with the other drug particles, thereby preventing eutectic formation and increasing product stability. More commonly used pharmaceutical polymers include sodium carboxymethyl cellulose, methyl cellulose, ethyl cellulose, hydroxypropylmethyl cellulose, cellulose acetate phthalate, carbamer, hydroxypropyl cellulose, hydroxyethyl cellulose, poly(vinyl alcohol), and polyvinylpyrrolidone.

Tonicity adjusters are nontherapeutic solutes that are added to aqueous drug solutions to increase their osmotic pressure to levels that are isotonic with body fluids (e.g., in parenteral, ophthalmic, or nasal solutions). The most common tonicity adjusters are dextrose (parenteral solutions), sodium chloride, and boric acid (ophthalmic solutions).

Emulsion excipients are ingredients that are added to the oil phase of emulsions to increase physical stability and obtain a more viscous or acceptable feel/taste. Such dosage forms can be used for dermal application (lotion, cream) or for oral medication. This type of excipient can also be added to greasy ointments bases. They include natural and mineral waxes (beeswax, paraffin); fatty acids (stearic, oleic), fatty alcohols (cetyl alcohol), and fatty acid esters (isopropyl palmitate); petrolatum; vegetable and mineral oils; and cocoa butter.

Polymeric excipients (protective colloids) are also used to increase the viscosity of the water phase of emulsions (e.g., sodium carboxymethyl

cellulose, methyl cellulose, alginic acid derivatives from seaweed, and gelatin). Emulsified creams and lotions also include poly(ethylene glycols) and polyhydric alcohols that act as humectants for creams. Primary emulsifying agents for o/w or w/o emulsions are surfaceactive agents that can be anionic, cationic, amphoteric, or nonionic (see page 18). They can also be used as wetting agents in solid – liquid suspensions. Protective colloid dispersions are also used in suspension technology to affect stability and taste or "mouth feel".

Suppository Base Excipients. Cocoa butter (theobroma oil) is available as a natural product for oil-base suppositories. Some commercially available bases can be considered to be semisynthetic cocoa butter; they are more stable and yield a whiter product than cocoa butter itself. Examples include Cotomer, a partially hydrogenated cottonseed oil (Procter + Gamble); Suppositol, a hydrogenated coconut oil triglyceride (Fritz Wetz); Wecobees, a series of triglycerides derived from coconut and palm kernel oil (Drew Chemical Corporation); and Witepsol, a series of triglycerides (Riches-Nelson Inc.).

Water-dispersible suppository bases include glycerogelatin (ca. 20 % gelatin, 70 % glycerol, 10 % water and drug) and blends of poly(ethylene glycols) of appropriate molecular mass to achieve appropriate consistency and form upon cooling.

Propellant Gases. Aerosol dosage forms for inhalation therapy or topical use utilize various propellant gases including hydrocarbons and fluorinated hydrocarbons (see section 3.7). Fluorinated hydrocarbons have been limited in use to medicated aerosols for metered-dose inhalers and contraceptive vaginal foams. Compressed nitrogen and carbon dioxide have also been used as aerosol propellants.

Solid Dosage Form Excipients. *Diluents*, such as lactose (water-soluble) and calcium phosphate (water-insoluble), are used to obtain convenient bulk and weight and as aids for homogeneous blending of solids.

Binders or granulating agents (e.g., gelatin, starch, and gum dispersions) add adhesiveness to powders to create granules for better flow and compression.

Disintegrating agents absorb water after the tablet or granule has been swallowed, causing swelling and eventual bursting or disintegration of the solid unit to powdered form. This increases the dissolution rate of the drug. Examples of such agents are corn starch, sodium alginate, and microcrystalline cellulose.

Glidant and lubricants ensure smooth and uniform flow of granulation blends from hoppers to dies (tableting) or capsule filling units. This is necessary for uniform dose and product weight. Anti-adherent (ejection) lubricants ensure the release of tablets from the metal surfaces of dies and compression punches. Examples of such excipients are talc, calcium, zinc, and magnesium stearate, stearic acid, corn starch, and colloidal silica.

Solid dosage forms (powders, granules, compressed tablets) that effervesce in water to create a carbonated solution before swallowing contain solid *effervescent excipients* that serve as sources of carbon dioxide and safe and nontherapeutic acid. Sodium bicarbonate is generally the carbon dioxide source; citric acid, tartaric acid, and/or sodium acid phosphate provide the acid source.

Colors, flavors, and surfactants (see page 18), can also be used.

6. Quality Assurance [41–43]

In the case of prescription drug products, the quality of a dosage form is measured by the degree to which it successfully delivers the prescriber's intent. In the case of over-the-counter or nonprescription drug products, quality is the functional result expected by the person selecting the product for self-medication. Quality is thus a gauge of the product's acceptability to the patient or user, its safety, and therapeutic effectiveness.

Several departments within a pharmaceutical company are involved in the design, formulation, and monitoring of quality parameters in dosage forms to assure satisfactory quality to patients, pharmacists, prescribers, and regulatory governmental agencies.

The *research and development units* establish the physical and chemical specifications for all of the product ingredients and packaging components. In conjunction with pilot-plant or scale-up personnel, they develop acceptable param-

eters for production processes and equipment. This includes their validation to ensure that they function as expected.

The major responsibility of the *production unit* is the preparation of the final product in a quality manner: measure and handling of ingredients, use of appropriate processes and equipment as documented in batch formulae, and packaging of the correct product in the correct package with correct labeling.

Quality control units are responsible for systems that measure the desired standards for a product. These include physical and chemical assays and measurements at three key points: raw materials, in-process, and final product. They also include documentation and audit of all pertinent records and usually the control of label distribution.

The *quality assurance unit* has the responsibility for the overall quality of its products. While this includes quality control's inspection, monitoring, and analytical responsibilities, it is more pervasive. It encompasses all personnel activities, processes, equipment, and facilities involved in the manufacture of drug products.

Regulatory concerns established by federal, state, and/or local agencies must also be satisfied, see also → Pharmaceuticals, General Survey and Development. Thus, for example, national compendia (e.g., U.S.P./N.F.) establish specifications for various ingredients and processes. In the United States, the Food and Drug Administration (FDA) approves all new drugs and monitors the quality of prescription and nonprescription drug products marketed in the United States. Several other U.S. regulatory items that affect the assurance of quality of drug products are:

1) Establishment of good manufacturing practices (GMPs) to control all aspects of manufacture that must be attended to in order to deliver high-quality, safe, effective drug products (equipment; building/facilities; control of containers, closures, packaging and labeling; production and processes; personnel; warehousing and distribution; records and reports; and salvaging of returned products)
2) Good laboratory and good clinical procedures (GLPs and GCPs) to ensure these respective procedures
3) State health and licensing agencies with parallel requirements for the manufacture of drug products within their boundaries, which generally are very similar to federal laws and regulations
4) Local government regulations

Ecological environmental regulations affect pharmaceutical production at all levels of governance. A major concern is the quality of sewage a manufacturing unit produces and its effect on water pollution. Similarly, air quality must be monitored in terms of gaseous or aerosol effluent.

7. Pharmaceutical Containers [44], [45]

Dosage form containers, including their closures (seals), should not react with nor sorb any of the product ingredients. Similarly, package components should not leach into the drug product and the containers should be impervious to the environment. Plastic containers should not be permeable to atmospheric gases nor to product ingredients. The closure should also be impervious to gases entering or leaving the product.

In some cases the drug product must be protected against light by the use of opaque or amber glass. The product should not alter the physical state of the container: for example, plastics should not soften, become tacky, nor become disformed. Parenteral containers and closures must maintain sterility until used. All this must be assured for the entire designated shelf-life of the product, throughout storage and use.

Plastics used for the packaging of pharmaceutical dosage forms include: low-density polyethylene, high-density polyethylene, poly(vinyl chloride), poly(vinylidene chloride), polypropylene, polystyrene, and polyterephthalates. They differ in barrier and permeability properties, plasticity, and resistance to fracture.

Glass used for pharmaceutical containers, including parenteral dosage forms that may be exposed to autoclave temperatures, has been classified by the U.S.P./N.F. (U.S.P. XXII). The classes differ in chemical composition and resistance to hydrolysis:

1) Type I: borosilicate glass, highly resistant

2) Type II: soda-lime glass, internal surfaces are treated (dealkanized) to make them more resistant to acid pHs, than Type III
3) Type III: soda-lime glass
4) Type NP: soda-lime glass for general purpose use (nonparenteral glass)

Type I is intended for parenteral dosage forms at all pHs. Type II is used to package acidic or neutral pH parenteral products. Type III is used for nonparenteral drug products, but may be used for parenteral packaging if appropriate tests show it to be suitable. Type NP is used widely for oral or external-use dosage forms.

Every new container and closure material must be tested thoroughly with the drug product it is intended to contain before wide-scale manufacturing and marketing occur. Such tests should stress the product container over a suitable range of temperature, relative humidity, and light exposure to assure stability and, hence, safety and effective therapeutic activity.

The U.S.P./N.F. specifies various tests for establishing acceptable standards for container materials. In parenteral drug products, for example, materials are tested for light transmission (glass and plastic), chemical resistance of glass (the powdered glass test), container permeation, and foreign particulate matter.

Liquid and solid dosage forms for nonparenteral use are generally NP glass bottles or bottles made of a plastic that does not allow excessive gas permeation. The closure should similarly allow very little or no gas leakage into the container nor leakage of water vapor or other product components (e.g., perfume ingredients) out of the container. These containers are designed either for multiple use or as one-time, unit-dose containers. Amber glass is generally used to reduce the exposure of product to light. Clear glass is used when the drug product is light stable and its clarity improves product appearance. Plastic containers are lighter in weight and thus less expensive to ship. However, plastics are usually poorly biodegradable whereas glass can be recycled.

Parenteral and ophthalmic drug products utilize both glass and plastics as container components. Small-dose injections are delivered from glass ampules or vials whereas large-volume parenteral products are packaged in glass bottles and flasks or nonrigid plastic bags. Prefilled glass or rigid plastic syringes and syringe – vial combinations are sometimes used. Ophthalmic containers contain dropper units attached to the cap closure, or the dropper unit may be part of a squeezable plastic bottle. Such containers should not contribute particulate matter to the drug product; their form and chemical composition should also be stable to the sterilization procedure used.

External-use products are also packaged in glass or plastic containers. These can be bottles for the delivery of liquid solutions, suspensions, or emulsified lotions. They can also be squeezable plastic containers with specially designed plugs to aid product delivery. Many lotions are thixotropic and the design of the container should assist product flow.

Semisolid *ointments, creams, and pastes* can be delivered from glass or plastic jars of various diameters. The product is applied with the fingers, and widemouthed jars facilitate product access. Collapsible tubes (plastic, metal; coated, uncoated) are also used to deliver semisolid products. Less contact occurs between product and fingers, product contamination during use is thus lower. Viscous liquids and creams can be delivered from bottles with pump devices.

Suppositories can be packaged in cardboard boxes and may be wrapped individually in foil. Some suppositories are molded in rigid, plastic, torpedo-shaped molds, which then act as part of the final container.

Pressurized pharmaceutical aerosols are packaged in various containers. They must be able to "contain" their contents safely under the pressures that develop during production, storage, and use. Glass bottles coated with thermoplastic poly(vinyl chloride) are used for solution drug products. The external plastic coating is a protective measure to prevent shattering if the bottle is dropped. Suspensions and semisolids are generally enclosed in opaque containers. Aerosol containers may also be made of metal, with aluminum used for oral products and tin-plated steel for topical drug production. To ensure stability, metal containers may be internally coated. These coatings must be acceptable in terms of safety and product compatibility.

The type of valve used depends upon the product use. It can be designed to deliver metered doses or to control the size of the delivered liquid droplets or solid particles. Various actua-

tors or adaptor units can be attached for different purposes (e.g., to obtain different spray patterns). Oral inhalations to medicate an asthma episode need specially designed mouthpieces. Some aerosols include a flexible plastic dip tube or standpipe as an attachment to the valve unit (Fig. 9). Semisolid products (pastes, viscous creams) may utilize a rigid, plastic, dome-shaped diaphragm that is pushed upward by the expanding propellant gases. Such products may also be enclosed in a flexible plastic pouch that is squeezed by expanding propellant. These adaptations ensure a more economical delivery of the product.

8. Development of the Ideal Drug Delivery System

Probably the most effective drug delivery system in use today consists of the intravenous administration of an appropriately formulated aqueous drug solution in a two-step procedure:

1) Intravenous administration of an initial or bolus dose of the solution to reach a therapeutically effective blood plasma concentration of the drug quickly
2) Subsequent intravenous administration of the drug solution at a delivery rate (drops per minute) that is adjusted to maintain the therapeutic blood plasma level for a long period of time (12 – 24 h)

Such a drug delivery system overcomes reduced bioavailability associated with the absorption of drug through membranes.

Delivery of a drug solution that is 100 % bioavailable by this method avoids the "peak and trough" effect in blood concentration produced by conventional, orally administered tablets taken every 4 – 6 h. The difference between the maximum and minimum blood levels achieved by the intravenous drug can be minimized by control of the drug concentration in the delivered solution and its delivery rate. This effect reduces the potential for toxicity and results in a lessening of the "peak and trough" effect and a steadier therapeutic response throughout the duration of pharmacologic activity.

Several drawbacks exist in the utilization of the intravenous bolus – drip drug delivery system as a widely employed, patient-accepted system, especially for the ambulatory ill:

1) Patient inconvenience and discomfort
2) Need for special equipment and personnel
3) Potential source of infection and vein irritation
4) Expense

However, the temporal pattern of such administration (short onset with an extended duration of effect) has served as a model for noninvasive drug delivery systems that overcome such disadvantages by controlled release (Section 7.1).

The use of the oral route of administration to achieve a systemic effect is much more acceptable than the parenteral route, except in cases such as emergency medication, during surgery, and in comatose patients. An oral dosage form that mimics the intravenous bolus – drip by delivering a steady and controlled release of drug to the blood would have a great advantage (Section 7.2.1). Other routes of administration mimic this intravenous system (e.g., transdermal patches, subcutaneous implants, and medicated intravaginal inserts, Section 7.2.2).

All conventional oral dosage forms have a more delayed onset of activity than an

intravenous bolus – drip administration since they must be transported across gastrointestinal membranes to reach the blood prior to distribution throughout the body. The sublingual route requires a somewhat shorter time to achieve the onset than the oral route. In order to mimic intravenous administration, release of drug from an oral dosage form and absorption (bioavailability) have to be designed so as to reduce the onset time.

In the drug delivery systems discussed above, the drug is distributed throughout the body before achieving its effective concentration at the desired site of pharmacologic activity. Tissues other than target tissues are therefore also exposed to various concentrations of the drug and pharmacologic responses may be elicited at other nondesired sites. This can result in unwanted side effects. For example, if the drug was to achieve a therapeutic effect at a particular organ innervated by the vagus nerve, undesirable responses could also occur at other organs controlled by vagal stimulation. This raises another concept in drug product development: targeted drug delivery in which the drug is released from the dosage form at a certain organ or tissue (site-specific release) or at a specific binding site within a tissue (receptor binding). Thus, systemically administered dosage forms would produce a highly localized effect (see Section 7.3). In the case of cancer chemotherapy, for example, side effects are many and serious, and such a drug delivery system would be extremely advantageous.

Ideal drug delivery systems should:

1) release a drug moiety to a target site, maintain therapeutic levels there for prolonged periods of time, and do so safely without side effects, by means of controlled-release technology;
2) have an onset of activity that approaches that of an intravenous bolus – drip;
3) be administered orally once a day, and be completely bioavailable to the target site;
4) be acceptable in terms of product elegance and utility to ensure compliance; and
5) be inexpensive.

While the development of drug delivery systems continues with the study of new technologies and materials, older concepts are being reinvestigated (e.g., medicated lollipops). The glycerogelatin base could perhaps be adapted for pediatric medication. Medicated, gummy "chews" could be used for administering vitamins, antipyretics, and cough and cold therapy to children too young to swallow or chew hard tablets or capsules and who refuse drops.

8.1. Controlled-Release Drug Delivery Systems

The ideal dosage form should deliver enough of its drug content to a specific pharmacodynamic site to achieve rapid initial onset of therapy. The therapeutic concentration should be maintained in a uniform, constant mode by slow release of the remaining portion of the drug over a period such that no more than two daily administrations (but preferably one) are needed. Furthermore, such a dosage form should be designed for oral administration and controlled release in the gastrointestinal tract to ensure good patient acceptance and compliance. In some instances where the biological half-life of the drug is $<$ ca. 6 h, the "loading" portion of the dose may not be necessary since the slowrelease technology should reach effective therapeutic concentrations effectively without it.

In some instances, a longer period of therapy ($>$24 h) may be desired from a single dose. This is not currently possible with orally administered dosage forms involving gastrointestinal release.

Transdermal controlled-release delivery from appropriate devices is a possible, noninvasive method for accomplishing such a therapy. Subcutaneous pellet implants, intravaginal insert devices, and portable or implanted infusion pump devices could be used as drug delivery systems for achieving therapy over several months. The infusion devices would need to have a built-in system of easily refillable drug reservoirs.

The design and manufacture of a controlled-release dosage form should produce a therapeutic plasma drug concentration at the site of activity followed by the maintenance of such a blood/target tissue level for an extended time period. Initial release of the drug to reach the therapeutic threshold concentration should be followed by constant, uniform release over a prolonged period. Once the initial threshold level is reached,

the amount of drug released, absorbed, and distributed to the site of action should equal the rate of drug removal resulting from metabolism and excretion.

The most appropriate means to accomplish controlled release is to develop a technology in which the drug release rate is constant and independent of the amount of drug at the release site throughout the therapy, i.e., zero-order release. Most currently available oral dosage forms designed for extended periods of therapy are not true zero-order systems but slow, first-order release systems that depend on the concentration of available drug at the release site (e.g., release from core matrices and coated pellets). (The "osmotic pump" tablet discussed in Section 7.2.1 provides zero-order release throughout most of the extended duration of activity it is designed to deliver.)

Research and development on controlled-release, oral drug delivery products began in the 1950s. Since then, the associated terminology has developed into a plethora of marketing phrases without strict standardization and sufficient attention to specificity of definition. Many terms have been used synonymously and, thus, inappropriately: sustained release/action (SR/SA); prolonged release/action (PR/PA); repeat action (RA); delayed action (DA); timed release (TR); and extended release/action (ER/EA). To avoid confusion, however, it is important to use these terms accurately within pharmaceutical and medical literature and especially in communication with health care personnel and patients [26], [27].

Initial differentiation must be made between conventional dosage forms and controlled-release products. The former are designed to release all of their active ingredients immediately for dissolution in body fluids; the latter release the drug in a controlled mode to extend the therapeutic response time and to deliver the drug to a desired target organ or tissue site. (Some controlled-release dosage forms may, however, release portions of the drug immediately to reach the onset of therapy more quickly.)

The term *controlled release* describes any drug delivery system that is used to adjust and control a therapeutic response, either temporally (extended duration) or spatially (site-specific, targeted delivery).

Figure 10. Blood drug concentration – time curves
A) Conventional oral product; B) Sustained release/prolonged release; C) Sustained release/controlled release; D) Repeat action with period of nontherapeutic response; E) Delayed action (coated enteric product)MTC = median toxic concentration;
MEC = median effective concentration

Sustained-release systems are designed to develop and maintain safe therapeutic responses at constant levels for extended periods that are some multiples of those achieved by conventional products (Fig. 10 A, B). With oral administration such periods can be 8 – 12 h, transdermal "patches" are effective for 24 h, and subcutaneous or intramuscular implant products can sustain therapy for 6 months or more. These systems are also termed controlled-release within the currently popular terminology if they in-

volve some precise technology that achieves or approximates a zero-order rate of drug release (Fig. 10 C).

The term *prolonged release* also refers to products designed to achieve extended periods of therapeutic response. Sometimes this term is used to refer to systems that provide a lower degree of precision than a zero-order drug release rate, and cannot therefore be considered true controlled-release systems. However, they can be considered and identified as sustainedrelease products. Hence, within such terminology sustained and prolonged release are synonyms when the rate of release is not zero order (Figs. 10 B, C).

Zero-order release technologies are most accurately described as sustained-release and controlled-release systems. Slow, first-order release systems are, however, best referred to as prolonged-release products.

Repeat-action oral tablets can be viewed as prolonged-release products, since they provide longer periods of therapy than conventional tablets (Fig. 10 D). However, the blood concentration – time curves for such products have two (or three) peak levels of blood concentration with intermediate periods where the blood concentration falls below the median effective concentration (MEC). A concentration above the MEC is not sustained throughout the entire expected therapeutic period; hence the term sustained-release to describe repeat-action tablets could be questioned.

Delayed-release or *delayed-action* oral products (Fig. 10 E) are conventional dosage forms that have been designed to release all of the drug content at one time after a delay period. Thus, enteric coated tablets are examples of delayedaction/delayed-release oral products because they begin releasing their drug content in the duodenum and not in the stomach.

Some researchers in the field feel that zero-order release has been overemphasized in the development of controlled-release products. Likewise, the overabundance of terms currently in use may confuse and distract attention from the objective of the controlled-release concept: the delivery of drugs by systems that provide excellent bioavailability to the systemic circulation for extended periods of time with targeted delivery to specific sites to eliminate both untoward side effects for the patient and undesirable effects of endogenous biochemicals upon the drugs [46].

Biotechnology has drawn attention to polyproteins, both endogenous and exogenous to the human body, as entities of therapy (e.g., insulin and growth hormone). They pose major problems of stability and effective delivery through biological membranes (i.e., bioavailability).

8.2. Sustained- or Prolonged-Release Technology

The advantages sustained- or prolongedrelease dosage forms include reduction of large fluctuations in blood concentration levels of the drug and longer duration of activity. This reduces side effects and increases patient compliance because fewer dosings are required each day.

8.2.1. Oral Sustained-Release Dosage Forms

The oral route of administration has received the greatest amount of developmental attention for sustained-release delivery systems. Oral sustained-release products mainly utilize diffusion-controlled or dissolution-controlled drug release technologies. Other systems include osmotic pump tablets, ion-exchange systems, and complexation.

The best candidates for inclusion in sustained- and prolonged-release systems are drugs that are uniformly well-absorbed throughout the gastrointestinal tract, that do not have long or very short biological half-lifes (i.e., between 2 and 8 h), and that are meant for maintenance therapy of chronic disease states (rather than for acute therapy).

Dissolution-Controlled Oral Dosage Forms. In these dosage forms the dissolution rate of the drug is decreased to maintain a sustaining concentration in the blood and at the site of activity for extended durations. This is achieved in three ways:

1) *Formation of Small Drug Beads with Differing Coating Thicknesses.* The beads dissolve in the gastrointestinal fluids at varying rates depending upon the coating thickness. The

coatings generally consist of lipoidal ingredients. The coated beads are encapsulated in gelatin shells or compressed into tablets.

2) Formation of Small, Layered Drug Beads. Drug layers are alternated with layers of rate-controlling cellulosic coatings (e.g., methyl cellulose). The outside layers can be the drug needed to reach the initial onset of activity; the remaining alternately coated layers produce the "pulsed intervals" of sustained release.
3) *Embedding of Drugs in Polymeric or Waxy Biodegradable Matrices.* Matrix dissolution products are obtained by compressing the drug with polymers (e.g., methyl cellulose, sodium carboxymethyl cellulose) or with hydrophobic waxy materials (e.g., glyceryl tristearate, cannuba wax) that are slowly biodegraded.

Diffusion-Controlled Oral Dosage Forms. Two major types of diffusion-controlled, sustained-release technologies have been described for oral administration: reservoir and matrix units.

Reservoir products utilize a central core (reservoir) of drug that is coated with a water-insoluble polymer (e.g., ethyl cellulose) through which the drug solution diffuses at a slow rate.

In the *matrix system* the drug is dispersed throughout a water-insoluble polymer matrix. The drug located on the outermost layer of the matrix is the portion that is initially exposed to the gastrointestinal fluids and dissolves first. As the gastrointestinal fluid penetrates the matrix more drug dissolves and diffuses out. The matrix may be a water-insoluble cellulosic polymer or a plastic [e.g., polymethacrylate, polyethylene, or poly(vinyl acetate)]. Gradumet (Abbott) is a tablet using a plastic matrix. Both the spent matrix of the matrix diffusion system ("ghost") and the empty membrane "sac" of the reservoir diffusion system pass through the gastrointestinal tract undissolved.

Hydrocolloid Matrix [29]. In this system the drug is incorporated within the hydrocolloid matrix of a tablet. The powdered drug is dispersed in a solid hydrocolloid (e.g., cellulolose polymers). Upon exposure to gastrointestinal fluids the drug – matrix combination floats, having a bulk density <1. The outer layer of the matrix swells, slowing inward penetration of water. The outer layer gradually erodes and a second layer then swells and erodes. During this process the drug continually dissolves and diffuses into the gastrointestinal fluid. Such a design allows the drug unit to stay in the stomach for a longer period than with a conventional tablet and release continues in the small intestine. This technology is termed "Valrelease" and was developed by Roche Laboratories for diazepam.

Figure 11. The OROS oral tablet system for prolonged and sustained therapy (courtesy of ALZA Corp., Palo Alto, California)
a) Delivery orifice; b) Semipermeable membrane; c) Osmotic core containing drug

Oral Sustained-Release Dosage Forms with Osmotic Control [29], [30], [47]. In this system osmotic pressure provides a driving force that produces zero-order controlled release. Tablets utilizing this technology contain a core of solid drug that is surrounded by a semipermeable membrane (e.g., ethylene – vinyl acetate copolymer or polypropylene) through which water can pass, but not the drug (Fig. 11). In the gastrointestinal tract, water flows through the membrane and dissolves the drug. The drug solution then exits at a constant rate through a laser-drilled hole in the tablet to the gastrointestinal lumen. This rate is controlled by the osmotic pressure developed by the drug solution.

The osmotic pressure concept for oral controlled-drug release was originally developed in the United States by the ALZA Corporation (OROS). In Elan's modification of this system (the multidirectional osmotic drug absorption system , MODAS), the enclosing membrane is permeable both to water and drug. Thus, water enters the unit to dissolve the drug and the drug solution then passes out through the membrane in multiple directions, not through a single port.

In another variation of this system (Alzet osmotic pump, Fig. 12) a drug solution (e) is encased in an impermeable but flexible membrane (b) within a small capsular device. An electrolyte (c) surrounds the internal portion of the device. Water enters the device through a rigid semipermeable outer membrane (d) and dissolves the electrolyte. This creates a constant osmotic pressure that presses on the enclosed drug solution, causing it to exit through an orifice. This osmotic pump device has not yet been used in oral dosage forms, but as subcutaneous implants in experimental animals. The device has about the same size as a 000 capsule (diameter 6.5 mm, length 25 mm) and can deliver 2.5 μL/h for four weeks.

Ion-Exchange Dosage Forms for Oral Sustained Release [48]. Cationic or anionic drugs can be complexed to appropriate ion-exchange resins and then encapsulated in gelatin shells or compressed into tablets. The drug is slowly released from the resin in exchange for ions in the gastrointestinal fluid, the rate depending on pH and electrolyte concentration. An example of this technology is the encapsulation of such resin complexes of amphetamine and dextroamphetamine. Recently products have become available (Pennkinetic, PennWalt Co., now owned by Fisons Corp.) that utilize very small drug – resin beads coated with a polymer (ethyl cellulose) that is not soluble in gastrointestinal fluids but through which water, electrolytes, and drug can diffuse. The beads can be suspended in viscous liquid formulations to provide up to 12 h of therapy (e.g., cough syrups). The coating also masks the somewhat unpleasant taste of the resins (Delsym Syrup, Fisons Corp.).

Chemical Complexation Dosage Forms for Oral Sustained Release [29]. A few drugs have been complexed with organic compounds (tannic or polygalacturonic acid, for example) and formulated into oral sustained-release products. These complexes have a low solubility that usually depends on pH. Slow dissolution in the gastrointestinal fluid provides the prolonged release pattern.

Bioadhesives [49]. Recent research concerned with achieving prolonged duration of activity in oral dosage forms has included investigation of bioadhesive compounds for attachment to the mucous membranes. Various polymers have been tested [e.g., sodium carboxymethyl cellulose, carbomer, hydroxypropyl cellulose, cross-linked poly(meth)acrylates]. Dosage forms utilizing such technology are envisaged as being attached to gastrointestinal or oral mucosal membranes and slowly releasing their drug content for systemic absorption. Thus, buccal tablets of various size and shape could be used, as well as dosage form units meant to be swallowed. If such units or portions of them could remain in place for long periods, the problem of gastric emptying time and overall gastrointestinal transit time as a limiting factor could be controlled.

8.2.2. Other Sustained- and Prolonged-Release Drug Delivery Systems [14–34]

There are several other sustained- and prolonged-release dosage forms that are not administered by the oral route:

1) Transdermal drug delivery
2) Vaginal inserts
3) Ophthalmic inserts
4) Parenteral implants and injections

Transdermal Drug Delivery Systems [30], [31], [50], [51]. Transdermal systems are dosage forms that are applied to intact, healthy skin to deliver their drug content percutaneously to the blood for a systemic, therapeutic effect with an extended duration of activity (e.g., 24 h). Until recently, transdermal systems were of two types: (1) drug release from a reservoir through a rate-controlling microporous semipermeable membrane made of ethylene – vinyl acetate copolymer or polypropylene (Fig. 13) and (2) direct drug release from a matrix directly to the epidermis (Fig. 14). These medicated reservoirs and matrices are attached to plastic "band-aid" type strips and can be used, for example, to administer therapeutic amounts of nitroglycerin to angina patients for periods >12 h. The drug diffuses from a matrix or through a membrane to the skin surface and then through the skin. As long as the concentration of the drug at the skin – drug interface remains constant,

the amount of drug in the unit does not affect the blood concentration. Such dosage forms are vastly different from the older, traditional plasters intended for local use (not systemic therapy). In such plasters the drug is embedded in an adhesive backing and no attempt is made to control the rate of drug release for prolonged action. For example, external analgesic drugs can be formulated so as to bring relief to some muscles.

Figure 12. The Alzet osmotic pump (courtesy of ALZA Corp., Palo Alto, California)

Figure 14. Transdermal patch using a matrix to control drug release (Nitrodisc, G. D. Searle; original form of Nitro-Dur, Schering – Key)
a) Occlusive outer backing; b) Absorbent pad; c) Adhesive; d) Foil base; e) Matrix (drug and excipient, semisolid formed)

The ALZA Corporation (1980) developed the first transdermal drug delivery system for scopolamine (Fig. 13). The product was designed to control nausea and motion sickness and was marketed by Ciba as Transderm Scop. With several excipients, the drug was contained in a fluid reservoir between an outer backing layer of aluminized polyester film and a microporous polypropylene membrane [52]. The membrane is covered externally with an adhesive for skin application. The adhesive contains sufficient impregnated drug to saturate the epidermis in contact with it and achieve a rapid onset of activity. Thereafter, the membrane controls the rate of drug diffusion to the skin to achieve prolonged therapy. This marketed unit has the appearance of a medium-sized "band aid" with an affixed pillow-shaped reservoir, resulting in the name "transdermal patch".

The transdermal system has since been used with several other drugs (e.g., nitroglycerin and estradiol). Other membrane materials have been used (e.g., an ethylene – vinyl acetate copolymer with the nitroglycerin product). Membrane polymers also include cellulose nitrate, cellulose acetate, polycarbonate, and polytetrafluoroethylene.

Another marketed version of a transdermal drug delivery product involves the use of a matrix and not a microporous membrane. One such product (Nitrodisc, G. D. Searle) utilizes a drug-impregnated, solid, silicone matrix that is bonded to an outer backing (Fig. 14). The drug is released by controlled diffusion to the skin surface. In a similar product developed by Key – Schering (Nitro-Dur) the matrix was a gellike structure made of polyvinylpyrrolidone poly(vinyl alcolhol), glycerol, water, lactose, and sodium citrate. This original Nitro-Dur form has been replaced by a new form in which

the nitroglycerin is dispersed in acrylic-based polymer adhesives that are applied to an outer backing, and the product has the appearance of a piece of tan-colored adhesive tape. A resin cross-linking agent is also added to the adhesive to obtain the desired rate of controlled, diffusive release of nitroglycerin.

Intravaginal/Intrauterine System (Inserts) [33]. ALZA Corporation has developed the "Progestasert", which is designed to release progesterone by slow diffusion through a rate-controlling membrane for several months. The progesterone reservoir is built in a T-shaped intrauterine device.

Ophthalmic Controlled-Release System [32]. ALZA Corporation also has developed an ocular sustained-release device for the treatment of glaucoma. Pilocarpine diffuses from a drug reservoir through rate-controlling membranes composed of an ethylene – vinyl acetate copolymer. Marketed by Ciba-Geigy, these "Ocusert" disks are placed under the lower eyelid and intended to release medication for several days (Fig. 15).

Figure 15. The Ocusert ocular therapy system for prolonged and sustained drug release after installation under the lower eyelid (courtesy of ALZA Corp., Palo Alto, California)
a) Transparent rate-controlling membrane; b) White ring of polymeric material; c) Drug reservoir film containing pilocarpine

Parenteral Sustained- and Prolonged-Release Systems [34]. Surgery or specialized injection equipment is required for *subcutaneous implants*. The implants are drug – polymer units designed for slow release of drug over prolonged periods (months). The polymers should be biodegradable; hydrogels and silicones have been used.

Parenteral administration of a drug as an intramuscular or subcutaneous *depot injection* can be used for extended periods of therapy. Such a formulation can be an oleoginous suspension or solution. The injected volume remains as a depot at the injection site and the drug slowly diffuses from it. The rate of drug release depends on the properties of the vehicles used (e.g., vegetable oils) and the drug.

Recent research concerning parenteral depot injections has involved use of colloidal dispersions for the depot unit. Depot injections of microencapsulated drug have been investigated; the polymeric coatings of the microcapsules act as membranes to control the dissolution and diffusion of drug.

Liposomes are of interest as components of site-specific or targeted drug delivery systems [27]. They are phospholipids that hydrate to form tiny sacs or vesicles (1 – 10 μm) with aqueous layers separating lipid layers. Liposomes can have a single internal aqueous compartment surrounded by a lipoid membrane or may be multilamellar structures composed of concentric lipid and aqueous layers. A drug added during liposome formation can be located within the aqueous compartment (hydrophilic drug) or become part of the lipoid layer (hydrophobic drug). Control of liposome vesicle size, as well as the chemical structure and properties of the phospholipid, can influence organ or tissue site disposition and drug release.

Microspheres (nanoparticles) are another area of current investigation as site-specific drug delivery systems [27], [53]. They have a diameter of 100 – 500 μm and are similar to liposomes in that they form colloidal dispersions which can be administered intravenously. They can be formed by a coacervation technique as employed in microencapsulation. Microspheres have been prepared from diverse matrix materials: lipoproteins, ion-exchange resins, ferromagnetic albumin, serum albumin, ethyl cellulose, gelatin, polystyrene, starch, polyacrylamide, and ferromagnetic alkylcyanoacrylate. The properties of microspheres (e.g., matrix material, size, density, cross-linking, molecular mass, drug concentration) affect the site, rate, and nature of drug release.

No liposome product is marketed currently. However, drug delivery is being investigated for parenteral (see Section 7.3), ocular, and inhalation administration. Similarly, no clinically proven drug product based on microsphere technology is commercially available yet. Proposed uses for microspheres and liposomes are similar, involving diseases of the reticuloendothelial systems (i.e., infections and cancers).

Circulating macrophages may also be able to assimilate such drug-rich particles for use within the vascular system. All such structures must be shown to exhibit matrix and lipid stability and purity, as well as drug stability within the structure. Particle size must also be strictly controlled.

Aqueous suspensions can be injected intramuscularly or subcutaneously to achieve prolonged therapy. For example, protamine, zinc, and insulin form a complex that slowly dissolves and acts for much longer periods than injections of simple insulin solutions. Control of the particle size of the suspended materials and their crystalline nature also contribute to the prolonged therapeutic pattern.

The parenteral use of a combination of an intravenous bolus injection with an intravenous drip (see section 7) achieves the goal of controlled, prolonged therapy as well.

8.3. Targeted Drug Delivery Systems [53–58]

A drug delivered by a conventional dosage form interacts with various complex molecules and cellular components and traverses different membranes before it accumulates a threshold concentration at the desired site of therapeutic activity. This diminishes its potential effectiveness and may cause undesirable results in other organ tissues. Thus, an ideal drug delivery system must include the concept of drug delivery to a specific (target) site, and only that site. Targeted delivery could possibly be achieved by attaching the drug to a "carrier". The drug – carrier unit should remain intact and not undergo reaction with any endogenous metabolites or cellular structures until it reaches its target site: a particular organ, type of cell, or subcellular unit.

Site-specific (targeted) drug delivery is different from conventional dosage forms that are delivered to an anatomical site to achieve a localized effect (e.g., suppositories to relieve local symptoms of hemmorhoids, eye drops for local ocular therapy, and creams or lotions to treat skin rashes). Site-specific drug delivery involves systemic administration of a drug – carrier/dosage form with the anticipated therapeutic activity targeted at a site away from the point of administration.

The drug – carrier unit should be able to "recognize" its target unit and release the drug entity in a controlled manner to achieve prolonged duration of activity. The carrier should then be biodegraded and pass out of the body without any further biochemical or pharmacologic intervention. An "ideal" carrier for targeted drug delivery should therefore have the following properties:

1) biodegradability,
2) high "carrying" capacity,
3) selective drug delivery,
4) reproducible properties,
5) nontoxic,
6) nonimmunogenic,
7) controlled release of drug,
8) long shelf-life, and
9) low production costs.

Recent research on site-specific drug delivery has involved a variety of carrier substances including plasma proteins, glycoproteins, polymers, monoclonal antibodies, and microparticulate carriers. This last group includes liposomes, microspheres, nanoparticles, and erythrocytes. Site specificity can vary depending on the delivery level achieved.

The term *passive targeting* is used when the drug – carrier unit passes through the same natural distribution pattern in the body that the carrier substance would normally take. An example of passive targeting is the intravenous injection of microparticles of a drug – carrier for delivery to subcellular lysosomes in macrophages within the organs of the reticuloendothelial system (liver, spleen, bone marrow).

Active targeting refers to drug – carrier distribution to the target site that is in some way altered from the normal distribution in the body of the carrier substance. The use of magnetic, biodegradable colloidal particles as carriers might be viewed as an example of the latter.

After intravenous injection, such a drug – carrier unit could be directed to the target site by an external magnetic device [59–61]. Once a suitable concentration has been achieved, the device then could release the drug at a controlled rate to achieve prolonged therapy.

1. Introduction

The pharmaceutical industry is largely a research-based industry. Not only has it been historically successful in providing valuable new medicines for treatment of diseases, but also its research and development laboratories have made significant contributions to our basic understanding of those diseases. In significant part because of the success of this industry, people today look forward to longer and healthier lives than ever before. Excellent reviews of this industry have been published [1, 2].

Historically, today's pharmaceutical industry emerged from a number of different sciences and approaches to finding therapeutics. Examples are: (1) the early discovery that extracts of plants such as salicylates from willow tree bark could provide products with medicinal value; (2) the discovery that proteins could be used as drugs, i.e., Banting and Best's demonstration that insulin could reverse the ravages of diabetes in 1938, and commercial expression of recombinant proteins such as tissue plasminogen activator (TPA) by Genentech; (3) Lister's small-pox vaccine and the development of the first monoclonal antibody therapeutic, OKT3, by Johnson & Johnson for prevention of tissue transplant rejection; (4) research in gene therapy; (5) use of genomics to find new targets for pharmaceutical intervention; and (6) the scientific approach which spawned most of today's pharmaceutical armamentarium – modification of organic molecules to provide therapeutically active agents through medicinal chemistry.

Active substances based on small organic molecules comprise the largest segment of available pharmaceutical products today. Other sources for active ingredients are biotechnological and biological materials, herbals, and plant extracts, homoeopathic as well as anthroposophical medicines. In some regions of the world, traditional medicinal products contribute to a large extent to the therapy of diseases, e.g., ayurveda in India or traditional chinese medicine (TCM).

In 2005, global sales for pharmaceutical products were estimated to be approximately US $ 602×10^9 [3]. This includes both medicinal products sold via prescription and directly by consumers, so-called "self-medication" or "over-the-counter" (OTC).

The pharmaceutical industry has features that distinguish it from other industries. First, this industry is research-intensive, having close interaction with universities and other research facilities. R & D is expensive, and the time needed for the discovery and development of new products typically long. Secondly, because of the enormous cost of pharmaceutical R & D, companies strive to market their products worldwide in order to recoup their R & D costs. Thirdly, this industry is heavily regulated, both in terms of requiring regulatory approval to market medicinal products and, in many countries, requiring price approvals. Price regulation is important not only because it affects profits and the ability to reinvest in new research within the pharmaceutical industry, but also because it relates to the cost of healthcare generally. Finally, physicians tend to be the customers rather than patients who actually use the pharmaceutical industry's products. As a result, a complex interaction exists with the medical profession, governments, and insurance groups that actually pay much of the cost of this industry's products in many countries.

Pharmaceutical products are one of the most efficient forms of therapy available today. Because of this success and the aging of the population, the percentage share of healthcare costs in GNP has grown.

2. Companies, Markets, and Products

The global pharmaceutical market is divided into two segments. One segment is medicinal products available only on prescription by a physician or other healthcare professional. The second segment is OTC products. These are generally well-established treatments for minor diseases, where safety and the ability to self-diagnose are of no concern. In this discussion of the pharmaceutical market, both segments are combined.

On a geographical basis, the sales figures for the major markets of medicinal products are shown in Table 1. These data show that the top six countries account for about 70 % of the worldwide market of US $ 601.3×10^9.

Table 1. World pharmaceutical market by country in 2005 [3]

Country	Sales (US \$ 10^9)
United States	252.2
Japan	67.7
Germany	31.9
France	30.3
Italy	19.8
United Kingdom	19.5
Spain	15.1
Canada	13.5
China	11.6
Brazil	9.1

If a breakdown of worldwide sales is made among companies, it can be seen that the top ten companies account for about 47% of the total audited market (Table 2). The remainder is supplied by a large number of smaller companies. Currently, the largest company in terms of worldwide sales covers just about 8 % of the total audited market. Obviously, many smaller companies still represent very significant businesses.

The major pharmaceutical companies maintain research facilities in a number of countries in North America, Europe and Asia and have multiple commercial operations throughout the world.

The global pharmaceutical market is divided into many therapeutic segments and classes. The largest class (Table 3) are cholesterol and triglyceride regulators, which accounted for approximately 5.7 % of the global market. Antiulcerants is the next largest segment, accounting for 4.7 % of the global market.

The top 10 branded medicinal products worldwide by sales in 2005 are shown in Table 4. Several points should be made. First, these sales figures are worldwide sales. The leading products in individual countries vary considerably because of differences in the incidence of diseases, medical practice, and the particular strengths of international and local companies in that particular market. Secondly, if prescription number rather than sales ranked the top 10 medicinal products, a somewhat different picture would emerge.

Table 3. Top five therapeutic classes of the pharmaceutical market in 2005 [3]

Therapeutic classes	Sales (US \$ 10^9)	% of Sales
Cholesterol & triglyceride regulators	32.6	5.7
Antiulcerants	26.9	4.7
Antidepress. & mood stabilizers	19.9	3.5
Antipsychotics	16.2	2.9
Erythropoietin products	12.4	2.2

Finally, most of the sales volumes discussed above relate to sales of pharmaceutical products based on prescriptions. There are also OTC products that are sold without a prescription. These products are commonly used for relatively minor diseases and have not only been shown over time to be safe and simple to use, but it has been concluded by regulatory authorities that no medical guidance beyond instructions on the package are needed by the patient to use the product correctly. The OTC company typically does not do innovative research to discover new active substances, but rather distributes well-established patent-free medicines directly to the consumer.

In the case of *prescription pharmaceuticals*, the research-based pharmaceutical company is the innovator of new pharmacologically active compounds known as new chemical entities (NCEs) or, to cover both small molecules and biotechnology products, new active substances (NAS). The research to discover a useful new active substance is expensive and lengthy, and the probability of success on any single project is

Table 2. Top ten pharmaceutical companies in 2005 [3]

Rank	Company	Country	Pharmaceutical sales [US \$ 10^9]
1	Pfizer	USA	47.7
2	GlaxoSmithKline	United Kingdom	34.9
3	Sanofi-Aventis	France	30.4
4	Novartis	Switzerland	28.7
5	Johnson & Johnson	USA	25.4
6	AstraZeneca	UK/Sweden	24.2
7	Merck & Co	USA	23.6
8	Roche	Switzerland	19.9
9	Abbott	USA	15.7
10	Bristol-Myers S.	USA	14.8

Table 4. Top 10 branded products by sales in 2005 [3]

Product	Active ingredient	Company	Sales (US \$ 10^9)	Disease
Lipitor	Atorvastatin Calcium	Pfizer	12.9	high cholesterol
Plavix	Clopidogrel bisulfate	Bristol-Myers Squibb & Sanofi-Aventis	5.9	heart disease
Nexium	Esomeprazole	AstraZeneca	5.7	heartburn
Seretide / Advair	Salmeterol xinafoate + fluticasone propionate	GlaxoSmithKline	5.6	asthma
Zocor	Simvastatin	Merck & Co.	5.4	high cholesterol
Norvasc	Amlodipine besylate	Pfizer	5.0	high blood pressure
Zyprexa	Olanzapine	Eli Lilly	4.7	schizophrenia
Risperdal	Risperidone	Johnson & Johnson	4.1	schizophrenia
Ogastro / Prevacid	Lansoprazole	Abbott & Takeda	4.0	heartburn
Effexor	Venlafaxine HCl	Wyeth	3.8	depression

low. Once a compound has been found, lengthy development studies are required to prove to regulatory agencies that the compound is safe and effective for use (Chap. 4) and of high quality. The time from initiation of a new research project to the marketing authorization can easily take 12–15 years and consume US \$ 850×10^6. This business requires high research investment over a prolonged period of time and will see a long delayed return on investment. The risks of failure are high, but the rewards for a successful product can also be high. These medicines are promoted primarily to medical professionals, citing claims approved by regulatory agencies, although direct to consumer advertising is sometimes also being used.

The *generic pharmaceutical industry* is another part of the pharmaceutical industry. Products that are the subject of current valid patents can be manufactured and marketed only by the patent holders or by a licensee. When the patents have expired, after 20 years of patent life in most countries, other manufacturers are free to manufacture and market the product if approved by regulatory agencies. Companies can sell these off-patent products as "generics". The same active ingredient can be used in generic products, but not with the same trade name because the innovator will typically own that. The generic business involves little research since it relies upon the research of others, and concentrates only on commercially successful products whose patents have expired. These products are still sold on prescription, usually at prices lower than the innovator since generic companies do not have to recoup extensive R& D expenses.

Finally, there are "active pharmaceutical ingredient" (API) suppliers, which manufacture and supply active substances and excipients to the pharmaceutical industry.

The pharmaceutical industry also can be said to include wholesale distributors and retail outlets.

3. Legal Requirements and Guidance

3.1. General

In almost all countries throughout the world, the development of pharmaceutical products, their manufacture, and marketing depend on governmental approval. Pharmaceutical products are regarded as being potentially dangerous. A comprehensive national legal framework, therefore, exists to avoid risks in connection with the development, manufacture, distribution, marketing, and use of medicines.

This chapter gives an overview of internationally and generally accepted legal requirements. It is based on the main laws of the United States (US) and the European Union (EU). In the following, law means legal provisions adopted by the legislative organ (i.e., parliament), regulation means legal provisions made by an institution of the executive (i.e., the government) on the basis and within the limits of an authorization given by the law. Administrative regulations are governmental measures directly binding not the individual or a company but the competent authorities.

United States Law. The basic law in the US is the *Federal Food, Drug, and Cosmetic Act* (FFDCA), as amended, the latest amendment being the *Food and Drug Administration Modernization Act of 1997* (FDAMA). Many regu-

lations have been issued relating to drugs based on this Act. The main regulations are:

1) Investigational New Drug Application (IND) [21 Code of Federal Regulations (CFR) Part 312]
2) Applications for FDA Approval to Market a New Drug (NDA) (21 CFR Part 314)
3) Protection of Human Subjects (21 CFR Part 50)
4) Institutional Review Boards (21 CFR Part 56)
5) Good Laboratory Practice for Non-Clinical Laboratory Studies (21 CFR Part 58)
6) Current Good Manufacturing Practice for Finished Pharmaceuticals (GMP) (21 CFR Part 211)

European Union. The legal system of the EU differentiates between regulations and directives, both issued by the Council of Ministers, the European Parliament, and occasionally by the Commission. Regulations have direct and binding effect in the member states, whereas directives have to be transferred separately into national law. The main regulations and directives are:

1) Consolidated Directive 2001/83/EC of the European Parliament and of the Council of 6 November 2001 on the Community code relating to medicinal products for human use as amended by Directive 2002/98/EC, Directive 2004/24/EC and Directive 2004/27/EC (http://ec.europa.eu/-enterprise/pharmaceuticals/eudralex/vol-1/-consol_2004/human_code.pdf)
2) Directive 2001/20/EC of the European Parliament and of the Council of 4 April 2001 on the approximation of the laws, regulations and administrative provisions of the Member States relating to the implementation of good clinical practice in the conduct of clinical trials on medicinal products for human use (Official Journal L 121, 1/5/2001 p. 34 – 44)
3) Commission Directive 2003/94/EC of 8 October 2003 laying down the principles and guidelines of good manufacturing practice in respect of medicinal products for human use and investigational medicinal products for human use (Official Journal L 262, 14/10/2003 p. 22 – 26)
4) Commission Directive 2005/28/EC of 8 April 2005 laying down principles and detailed guidelines for good clinical practice as regards investigational medicinal products for human use, as well as the requirements for authorization of the manufacturing or importation of such products (http://ec.europa.eu/-enterprise/pharmaceuticals/eudralex/vol-1/-dir_2005_28/dir_2005_28_en.pdf)
5) Regulation (EC) No 726/2004 of the European Parliament and of the Council of 31 March 2004 laying down Community procedures for the authorization and supervision of medicinal products for human and veterinary use and establishing a European Medicines Agency (Official Journal L 136, 30/4/2004 p. 1–33)
6) Commission Regulation (EC) No 1084/2003 of 3 June 2003 concerning the examination of variations to the terms of a marketing authorization for medicinal products for human use and veterinary medicinal products granted by a competent authority of a Member State (Official Journal L 159, 27/6/2003 p. 1–23)
   Commission Regulation (EC) No 1085/2003 of 3 June 2003 concerning the examination of variations to the terms of a marketing authorization for medicinal products for human use and veterinary medicinal products falling within the scope of Council Regulation (EEC) No 2309/93 (Official Journal L 159, 27/6/2003 p. 24–45)

The most relevant guidance documents for marketing authorizations for medicinal products for human and veterinary use in the member states of the EU have been published by the European Commission under the title "The Rules Governing Medicinal Products in the European Union" in 9 volumes (http://ec.europa.eu/enterprise/pharmaceuticals-/eudralex/index.htm).

International Harmonization A very important attempt has been made to harmonize the scientific/technical standards defining the type and amount of studies necessary to confirm the quality, safety, and efficacy of new medicines. This attempt is called "International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use" (ICH). Since 1991, ICH has successfully developed and published numerous guidelines in a joint effort by regulators and industry experts from the European

Union, Japan, and USA (http://www.ich.org/-cache/compo/276-254-1.html). ICH guidelines do not legally bind the national authorities but are adopted and transferred into national guidelines in many countries both within and outside the ICH region.

3.2. Definitions

A *pharmaceutical product* is defined as the dosage form in the final immediate packaging intended for marketing (ICH Q1A).

A *dosage form* is a pharmaceutical product type (e.g., tablet, capsule, solution, cream) that contains an active substance generally, but not necessarily, in association with excipients (ICH Q1A).

An *active substance* is defined (Directive 2001/83/EC) as either

a) any substance or combination of substances presented as having properties for treating or preventing disease in human beings; or
b) any substance or combination of substances which may be used in or administered to human beings either with a view to restoring, correcting, or modifying physiological functions by exerting a pharmacological, immunological, or metabolic action, or to making a medical diagnosis.

An active substance can be any matter irrespective of origin, which may be:

- human, e.g., human blood and human blood products;
- animal, e.g., microorganisms, whole animals, parts of organs, animal secretions, toxins, extracts, blood products;
- vegetable, e.g., microorganisms, plants, parts of plants, vegetable secretions, extracts;
- chemical, e.g., elements, naturally occurring chemical materials and chemical products obtained by chemical change or synthesis.

Quality is the suitability of either an active substance or a pharmaceutical product for its intended use (ICH Q8).

Safety means that, in the light of currently prevailing scientific knowledge, the pharmaceutical product has no harmful effects exceeding medical acceptability.

Efficacy means a reasonable expectation that, in a significant proportion of the target population, the pharmacological effect of the pharmaceutical product, when used under adequate directions for use and warnings against unsafe use, will provide clinically significant relief of the type claimed [21 CFR 330.10].

Side effects mean the occurrence of undesired reactions.

3.3. Requirements Relating to the Development of Pharmaceutical Products

Before a pharmaceutical product can be put on the market, various prerequisites have to be fulfilled notwithstanding the necessary final marketing authorization. These prerequisites relate to the testing of the pharmaceutical product. The performance of testing is not within the free discretion of the pharmaceutical company or the investigator. Internationally accepted standards and methods have to be applied. The testing program is divided into chemical-pharmaceutical development (see Section 4.3), pharmacological and toxicological studies (see Section 4.1), and clinical trials (see Section 4.2).

3.4. Marketing Authorization

The placing of pharmaceutical products on the market needs governmental approval as defined in relevant national laws. Such an approval generally needs proof of quality, safety, and efficacy of the pharmaceutical product. The competent authority has to give its approval on the basis of evidence provided during the development phases. Within the EU, a distinction has to be made between two procedures: a centralized procedure, which exclusively applies for medicinal products, derived from biotechnology and for new active substances. A marketing authorization granted under the centralized procedure is valid for the entire community market, which means the medicinal product may be put on the market in all EU member states. In addition, the procedure of mutual recognition exists meaning that normally a member state is bound by an approval of another member state in the sense that it recognizes that approval as basis for its own

identical decision. The approval, however, remains national (The Rules governing Medicinal Products in the European Union, Volume 2A, Notice to Applicants – Procedures for marketing authorization: http://ec.europa.eu/enterprise/-pharmaceuticals/eudralex/homev2).

If minor changes are made to the documentation already submitted to the health authority, the applicant has to notify the authority of these changes. Major changes (e.g., dosage, duration of application, limitation of contraindications, side effects, or interactions) have to be approved by the authority.

The competent authority is entitled to withdraw, revoke, or suspend the authorization given at any time if there are special reasons relating to the quality, especially to the safety or to the efficacy of the pharmaceutical product.

Unless previously prolonged, the marketing authorization expires in some countries after a defined period.

3.5. Requirements for the Manufacture and Quality Control of Pharmaceutical Products

The manufacture of pharmaceutical products may itself involve risks. The quality of the product has to be identical to that accepted by the authority responsible for the marketing authorization. Consequently, the manufacturer needs special governmental authorization to produce pharmaceutical products. The requirements to be met by the applicants are suitable and sufficient premises, technical equipment, and control facilities as well as, according to EU regulations, at least one appropriately qualified person responsible for production, i.e., the production director. The qualified person is usually a pharmacist, but chemists, biologists, physicians, and veterinarians are also admitted provided that they have acquired additional knowledge and experience specified in the relevant law. The qualified person has to be permanently present during formulation.

An additional, very important requirement for the manufacturer of pharmaceutical products is observance of the rules of Good Manufacturing Practice (GMP). These rules relate to quality assurance system, personnel, premises, equipment, documentation, production, quality control, contract manufacture and analysis, complaints, product recall, and self-inspection. These principles are laid down in Volume 4 of the Rules Governing Medicinal Products in the European Union "Medicinal Products for Human and Veterinary Use: Good Manufacturing Practice" (http://-ec.europa.eu/enterprise/pharmaceuticals/-eudralex/homev4.htm), and for the US in 21 CFR Part 210 (http://www.access.gpo.gov/-nara/cfr/waisidx_06/21cfr210_06.html) and 211 (http://www.access.gpo.gov/nara/cfr/-waisidx_06/21cfr211_06.html).

A GMP guideline for active substances has been developed by ICH: Good Manufacturing Practice Guide for Active Pharmaceutical Ingredients – Q7 (http://www.ich.org/-LOB/media/MEDIA433.pdf)

The manufacturing, control, storage, packaging, and marketing of pharmaceutical products are subject to supervision and inspection by the competent authority. This authority varies from country to country; it may be a central governmental authority or the authority of a federal state. The manufacturer has to give the inspectors of the authority access to the premises in which pharmaceutical products are manufactured. This also holds for the manufacture of active substances. The development of pharmaceutical products and their clinical testing are also supervised by the competent authority, which has to check whether the legal requirements for clinical trials have been met. The law gives the competent authority various authorizations to ensure adherence to the laws and regulations.

3.6. Requirements for Placing a Pharmaceutical Product on the Market

The most important legal prerequisite for placing a pharmaceutical product on the market is the marketing authorization. However, many other stringent provisions also have to be observed. Most pharmaceutical products can only be sold to the patient by a pharmacy. This applies to pharmaceutical products prescribed by a physician and to non-prescription (over-the-counter, OTC) products. The OTC products are generally recognized as safe and effective and not misbranded if certain conditions are met, especially

with respect to any applicable monograph (21 CFR Part 330). Some information has to be declared on the package (e.g., name and address of the manufacturer, name of the pharmaceutical product, registration number, batch number, type and amount of active ingredients, expiry date). The most important source of information for the patient, however, is the package insert, which contains instructions for use and a description of indications, contraindications, side effects, and interactions. Comprehensive scientific written information must also be available in written form for doctors and physicians. If the pharmaceutical company wants to promote the pharmaceutical product, compulsory information on the product has to be given. This information is almost identical to that contained in the package insert.

All these and additional information instruments are designed to avoid risks in connection with the administration of pharmaceutical products, and to guarantee maximum safety. The competent authority is entitled and authorized to control and inspect the company to make sure that it complies with the law.

An additional legal obligation of the pharmaceutical company is to report all possible side effects of the pharmaceutical product, whether previously known or unknown, to the competent authority without undue delay. Every pharmaceutical company has to have a special safety monitor whose function is to collect and to evaluate reports on side effects and to coordinate the necessary measures. The safety monitor is personally responsible for the fulfillment of the notification obligations toward the health authority and must be a physician, veterinary physician, or pharmacist with at least two years professional experience. The name of the person must be notified to the competent authority. Another specialist to be appointed by the pharmaceutical company has to guarantee for the authenticity of the product information used with the data contained in the registration file.

3.7. Liability

If, as a result of the administration of a pharmaceutical product, a person is killed or the body or the health of a person is considerably injured, then the pharmaceutical company that has placed the pharmaceutical product on the market is obliged to compensate for the harm caused by the injury. This liability is independent of fault and not imposed on the manufacturer, but on the company placing the product on the market. Liability only exists if the pharmaceutical product, despite correct use, produces harmful effects that exceed the bounds considered justifiable in the light of scientific knowledge available in medical science and which have their origin in the development of the pharmaceutical product or the manufacturing processes, or if damage has occurred as a result of formulation or instructions for use that do not comply with the knowledge available in medical science. In general liability insurance is compulsory to cover the potential financial risk.

Finally many penal provisions and administrative fines complete the instrumentarium of the law; in many cases violation of the law leads to personal responsibility and liability.

3.8. International Non-Proprietary Names (INN)

International Non-Proprietary Names (INN) were introduced in 1950 for the purpose of creating an unambiguous single non-proprietary name for active substances worldwide. (WHO Drug Information vol. 13, no. 1, 1999, pp. 13 – 14). The World Health Organization (WHO) is in charge of selecting a single name, which is acceptable all over the world for each active substance, which is to be marketed as a pharmaceutical product. Trademarks for medicines are not allowed to be similar to INNs so as not to confuse the patients or doctors.

In order to select an INN, a request is usually submitted to the WHO on an INN request form. In certain countries where national nomenclature commissions exist, this is done through the national nomenclature authority, e.g., in the United States it is the United States Adopted Names (USAN) Council. Precise information on the substance's chemistry, pharmacological action and therapeutic use must be provided. The proposed non-proprietary names and the name and address of the manufacturer are also entered in the form.

The names proposed by the originator are examined and one name is selected in accor-

dance with the "Procedure for the selection of recommended international non-proprietary names (INN) for pharmaceutical substances" and the "General principles for guidance in devising INNs". All the members of the WHO Expert Panel on International Pharmacopoeia and Pharmaceutical Preparations designated to select non-proprietary names have to agree to the name selected. Then it is first published as a *proposed INN*. During a four-month period, any person can forward comments, or lodge a formal objection to a name, e.g., on grounds of similarity with a trade name. If no objection is raised, the name will be published a second time as a *recommended INN*.

About 8000 INNs have been published to date (2006) in the "WHO Drug Information" journal. The names are given in English, French, and Spanish, as well as Latin. A cumulative list of all INNs is published periodically and includes INNs in Russian, as well as references to other common names (http://www.who.int/medicines/services/inn/en/).

4. Development of Pharmaceutical Products

4.1. Preclinical Safety/Toxicology

Preclinical disciplines as pharmacology, pharmacokinetics, and toxicology contribute to the evaluation of efficacy and safety of pharmaceutical compounds. There is no absolute safe administration of pharmaceutical drugs possible, but the experimental studies of toxicology facilitate to find the right path between safety issues for human use.

The toxicologist designs in vitro and in vivo studies to support the identification of unexpected and undesirable adverse effects of pharmaceutical or chemical compounds; the hazards should be described, the type and severity of toxicity should be analyzed, and the possible risks involved assessed. These objectives in toxicology help clinicians to design their clinical trials optimally, to use preclinical recommendation which biomarkers should be applied for human conditions and therefore support to manage the risks in humans when participating in clinical trials or later as patients after market authorization. An additional aim today in toxicology is to investigate the mechanisms behind changes observed, e.g., to explain why alterations appear in animals and possibly not in humans. This knowledge is relevant for doctors and facilitates the approval process by regulatory reviewers.

To identify risks and for using compounds safely, a great number of in vitro and/or in vivo experiments needs to be conducted. Test strategies for toxicological investigations have been refined and the extrapolation of preclinical results to humans improved. The prevention of toxic events in man is constantly the main goal in preclinical areas.

Today, toxicology is complex, expensive, and time-consuming. In former decades, considerable regulatory differences existed among different regions which led to unnecessary repetitions of studies without improving the safety profiles but increasing often unnecessarily the number of animals being used. Accordingly, public resistance and concerns among researchers increased the desire to harmonize test procedures and recommendations worldwide. Therefore, the International Conferences of Harmonization (ICH) were founded in 1989, which focus on the creation of guidelines to harmonize the testing procedures on an international basis.

Herein, the detailed requirements for preclinical studies to move the development of compounds into human clinical trials and finally to submit an approvable dossier to the regulatory agencies is described. The ICH guidelines outline the basic principles. For pragmatic recommendations when designing individual studies, additional guidelines like those published by the European Medicines Agency (EMEA) of the Food and Drug Administration (FDA) or WHO need to be considered too.

4.1.1. Preclinical Safety

The international discussions among experts have led to constructive solutions and recommendations, which are published in the ICH Guidelines (Table 5). These guidelines have been implemented practically worldwide, they provide excellent basic information, and stimulate new thinking to improve strategies or techniques, all with one objective: to be more predictive in regard to safety for human conditions.

Table 5. guidelines for the area of preclinical safety

ICH No.	Title	CPMP Doc. No.	Step
S1A	The Need for Carcinogenicity Studies of Pharmaceuticals	CPMP/ICH/140/95	Step 5

S7B	Safety Pharmacology Studies Assessing the Potential for Delayed Ventricular Repolarization (QT Interval Prolongation) by Human Pharmaceuticals	CPMP/ICH/433/02	Step 5
S8	Immunotoxicity		Step 5

Table 6 summarizes the guidelines which have been agreed upon multidisciplinary subjects. This multidisciplinary guidance helps to find useful concentrated information about what to do during which timeframe to decide which studies should be conducted when and finally where in the dossier to report them.

4.1.2. Toxicological Strategies

In general, investigations are done always as early as possible, but compound availability limits these objectives. In reality, strategies follow the principle of a step-by-step procedure. When small amounts of compounds are available then the safety of those people being exposed first with the drug (in the chemical laboratories) is in the foreground. Accordingly, short-term tests to analyze the toxicity and exclude genetic damages are being conducted very early on and only later when grams and kilograms of compound are available, more complex and long-term studies such as carcinogenicity studies are being performed. This strategic principle is not followed in the sequence of issues being dealt with within the ICH process: here the most urgent issues were discussed first and guidelines finalized.

The requirements for the first step, the New Investigational Drug (IND), to move the drug from preclinical activity into the clinics are:

- Toxicokinetics/pharmacokinetics

Table 6. Guidelines for multidisciplinary subjects

ICH No.	Title	CPMP Doc. No.	Step
M1	Medical Terminology: Medical Dictionary for Regulatory Activities Terminology (MedDRA)		
M2	Recommendations on Electronic Transmission of Individual Case Safety Reports Message Specification	CPMP/ICH/285/95	Step 5
M3 (M)	Non-Clinical Safety Studies for the Conduct of Human Clinical Trials for Pharmaceuticals (Modification)	CPMP/ICH/286/95	Step 5
M4	Common Technical Document for the Registration of Pharmaceuticals for Human Use	CPMP/ICH/2887/99	Step 4

- Short-term toxicity studies (single- and up to four-week studies)
- Local tolerance
- Genotoxicity in vitro (in vivo)
- Phototoxicity

The recommendations for the final process, the New Drug Application (NDA), in order to gain the market authorization include

- single- and repeated-dose toxicity studies
- reproduction toxicity studies
- genotoxicity studies
- assessment of carcinogenic potential
- local tolerance studies
- pharmacokinetic (absorption, distribution, metabolism, excretion; ADME) studies
- immunotoxicology studies
- studies on special populations, e.g., children

4.1.3. ICH Guidelines for Carcinogenicity

Guideline on the Need for Carcinogenicity Studies of Pharmaceuticals (ICH S1A). The objectives of carcinogenicity studies are:

- To identify a tumorigenic potential in animals
- To assess the relevant risk for humans.

Any cause for concern derived from laboratory investigations, animal toxicology studies, and data in humans may lead to a need for carcinogenicity studies.

Carcinogenicity studies should be performed for any pharmaceutical when the expected clinical use is continuous for at least six months or repeatedly in an intermittent manner. Examples of such conditions include allergic rhinitis, depression, and anxiety.

Pharmaceuticals administered infrequently or for short duration of exposure (e.g., anesthetics and radiolabel imaging agents) do not need carcinogenicity studies unless there is cause for concern, e.g., previous demonstration of carcinogenic potential in the product class or long-term tissue retention of parent compound or metabolite(s) resulting in local tissue reactions or other pathophysiological responses. Further, no cancerogenicity studies are needed for unequivocally genotoxic compounds, because it is assumed that such compounds will be positive for the cancerogenic potential also and these characteristics do not need to be proven. Further, pharmaceuticals showing poor systemic exposure from topical routes in humans may not need studies by the oral route to assess the carcinogenic potential to internal organs. Finally, carcinogenicity studies are not generally needed for endogenous substances, when given essentially as replacement therapy (i.e., physiological levels).

Testing for Carcinogenicity of Pharmaceuticals (ICH S1B). The regulatory requirements to assess the carcinogenic potential was the conduct of long-term carcinogenicity studies in two rodent species, usually the rat and the mouse. It was the mission of ICH to examine whether this practice could be reduced without compromising human safety for new compounds.

The results of a number of databases forced to rethinking of the historical strategies and led to the concept of a new paradigm as a new experimental approach to testing for carcinogenic potential. Thus, the basic principle for testing the carcinogenic potential is

- one long-term rodent carcinogenicity study plus

- one short- or medium-term study that supplements the long-term carcinogenicity study and provides additional information not readily available from the long-term assay.

Additional tests may include either short- or medium-term in vivo rodent test systems, in most cases using the mouse. These models of carcinogenesis may use transgenic or neonatal rodents. The ICH guideline includes also models of initiation/promotion in rodents; these models are considered today as useful models for hepatic carcinogenesis or adequate mechanistic studies but not as assays appropriate as general screen for drug-induced carcinogenesis.

A long-term carcinogenicity study in a second rodent species (e.g., mice) is still considered acceptable.

In the "Notes", the guideline describes some important information about the new models, e.g., Note 2 sets the conditions to limit testing with one species only. If the findings of a short- or long-term carcinogenicity study, genotoxicity tests, and other data would indicate that a pharmaceutical clearly poses a carcinogenic hazard to humans, usually a second carcinogenicity study would not be useful.

Note 3 provides details about the short- or midterm models. Representative approaches for testing the carcinogenic potential that may meet these criteria are:

- Several transgenic mouse assays including
  - p53+/− deficient model
  - Tg.AC model
  - TgHras2 model
  - XPA deficient model, etc.
- The neonatal rodent tumorigenicity model

According to their mechanism, these new models are characterized as follows:

- *Activated oncogenes*
  - TgHras2 model (Japan)
  - Tg.AC skin model (USA); also gavage
- *Inactivated tumor suppressor gene*
  - p53 "knock out" (=p53+/−) model (USA)
- *Inactivated DNA repair gene*
  - XPA-/- (NL)

Evidence of tumorigenic effects of the drug in rodent models should be evaluated in the light of the tumor incidence and latency, the pharmacokinetics of the drug in the rodent models as compared to that in humans, and data from any ancillary or mechanistic studies that are informative with respect to the relevance of the observed effects to humans.

The results from any test cited above should be considered as part of the overall "weight-of-evidence" evaluation, which takes into account the scientific status of the test systems.

These new models have been accepted by regulatory agencies. The assessment of the FDA of the new models in respect to the assay selection is as follows:

p53+/−	if clearly or equivocally genotoxic
TgAC	for dermally applied products
TgRasH2	for genotoxic or nongenotoxic products
Neonatal	if clearly or equivocally genotoxic

The assessment of the EMEA of the new models (EU: evaluation in the Safety Working Party of EMEA) is as follows:

- p53 and Tg.RasH2 are equally sensitive to genotoxic compounds (some false positives and false negatives)
- TgRasH2 is more sensitive to peroxisome proliferators
- p53 and TgRasH2 are acceptable in a regulatory context

Dose Selection for Carcinogenicity Studies of Pharmaceuticals (ICH S1C). The maximally tolerated dose or minimum toxic dose (MTD) method is still the standard method for high-dose selection.

The MTD is generally chosen based on data derived from toxicity studies of three months duration. The testing options for dose-range finding studies are:

- Usually:
  - 3 months for long-term studies
  - 1 month for neonatal- or transgenic-mice studies
- Range of different dose levels, often five
- Focus on toxicity endpoints, determination of MTD
- Profiling of the Area Under the Concentration-versus-Time Curve (AUC)
  - e.g., 1 and 3 months for rats
  - e.g., 1 and 4 weeks for alternatives
  - transgenic = wild type

The long-term carcinogenicity studies are designed as follows:

Species:	rats, mice, rarely hamster
Duration:	24 months rats, 24 months mice
Route:	as in clinical conditions, in feed, water, by gavage, inhalation
Dose levels:	mostly 3, mostly with a factor (e.g., 1:3:9)
Animal numbers	50/group/sex
Results available	prior to NDA
Costs	€ $1.0–1.5 \times 10^6$

The selected dose levels for rodent bioassays should provide a high enough exposure to the agent, and an adequate margin of safety. No significant physiological dysfunction should be induced and the toxicity should be compatible with two years survival. The criteria of choosing the high dose are:

- MTD
- 25-fold AUC ratio (rodent:human)
- Dose-limiting pharmacodynamic effects
- Saturation of absorption
- Maximum feasible dose

The MTD is the most frequent criteria used for the top dose. A minimum toxic effect over the course of the carcinogenicity study is the objective. Such MTD is defined, e.g., by no more than 10 % decrease in body weight gain relative to that of controls.

The second alternative for relatively well tolerated drugs is a systemic exposure representing a 25-fold multiple of the human AUC. Saturation of absorption measured by systemic availability of drug-related substances is also acceptable as a limit dose. Finally, the pharmacodynamic effects may limit the high-dose selection. If a compound, for example, reduces the blood glucose level, then exaggeration is detrimental.

The maximum feasible dose by dietary administration was considered 5 % of diet, but this amount of drug was considered to be too high. Therefore, a new and more reasonable solution was formulated in the Guideline ICH S1C(R).

Addendum to Dose Selection for Carcinogenicity Studies of Pharmaceuticals: Addition of a Limit Dose and Related Notes of Pharmaceuticals (ICH S1C(R)). In determining the high dose for carcinogenicity studies, it may not be necessary to exceed a dose of 1500 mg/kg/d. This limit dose applies only in cases where there is no evidence of genotoxicity and where the maximum recommended human dose does not exceed 500 mg/d.

4.1.4. ICH Guidelines for Genotoxicity (ICH S2A and ICH S2B)

The Genotoxicity Guidelines ICH S2A and ICH S2B (Table 7) deal with the avoidances of DNA damage. Compounds used for human treatment should not induce tumors or teratogenicity.

The recommendations help to conduct studies with acceptable meaningful approaches. It is requested to provide good information on the potential to induce gene mutations, structure chromosome aberrations (clastogenicity), and numerical chromosome aberrations (aneugenicity).

No single test is capable of detecting all relevant genotoxic agents and therefore, a battery of tests is considered appropriate.

The Standard Battery consists of three assays:

1) Test for gene mutations in bacteria (Ames)
2) An in vitro test with cytogenetic evaluation of chromosomal damage with mammalian cells *or* an in vitro mouse lymphoma *tk* assay
3) An in vivo test for chromosomal damage using rodent hematopoietic cells.

The in vitro tests are carried out with and without extrinsic metabolic activation, usually provided by a rat liver S9-mix.

The ICH Guidelines inform about the top concentrations for in vitro tests and the expected levels of cytotoxicity, about repeat or confirmatory testing, and the proof of target tissue exposure to the test article in the in vivo studies. Support can be found for the interpretation of positive test results and considerations on conditions leading to false positive data.

4.1.5. ICH Guidelines for Toxicokinetics/Pharmacokinetics (ICH S3A and ICH S3B)

With the data of toxicokinetics, one describes the systemic exposure achieved in animals and humans and its relationship to dose level and the time course of the toxicity study. The exposure is related to the toxicological findings and to the relevance of these findings related to the clinical safety.

The kinetic information of the parent compound and its metabolites contribute to the extrapolation of safety from animals to humans.

Table 7. Guidelines for genotoxicity aspects

ICH No.	Title	CPMP Doc. No.	Step
S2A	Genotoxicity: Guidance on Specific Aspects of Regulatory Genotoxicity Tests for Pharmaceuticals	CPMP/ICH/141/95	Step 5
S2B	Genotoxicity: A Standard Battery for Genotoxicity Testing of Pharmaceuticals	CPMP/ICH/174/95	Step 5

Species differ considerably in regard to their kinetic conditions, measured as Cmax, Tmax, AUC, $t\frac{1}{2}$, and ADME.

As far as possible, kinetic analyses should be integrated into preclinical safety studies. Therefore, the provision of kinetic data should be considered in the following study types: repeat-dose toxicity studies, genotoxicity in vivo studies when there are differences between in vitro and in vivo results, possibly reproductive toxicity studies, and cancerogenicity studies where monitoring is recommended to be appropriate but not beyond six months duration. It is important to demonstrate exposure and, e.g., inhibition or accumulation. The latter may explain toxicity at the site of increased compound accumulation.

Single-dose studies provide usually sufficient information about tissue distribution but there may be cases where assessments after repeated dosing may provide better information. Such studies are necessary when

- single-dose distribution studies suggest that the half-life of the test compound and/or metabolites in organs or tissues significantly exceeds the half-life of the elimination phase in plasma;
- steady-state levels of a compound/metabolite in the circulation, determined in repeated dose pharmacokinetic or toxicokinetic studies, are markedly higher than those predicted from single-dose kinetic studies;
- histopathological changes were observed that were not predicted from short-term toxicity studies.

This information is provided in the ICH guideline S3B: "Pharmacokinetics: Guidance for Repeated-Dose Distribution Studies (CPMP/ICH/395/95)".

4.1.6. ICH Guidelines for Reproductive Studies (ICH S5A and ICH S5B)

The special toxicology discipline "Reproductive and Developmental Toxicity" focuses on undesirable adverse effects on male and female fertility, birth defects (developmental toxicity, malformations, teratogenicity), and nonphysiological changes that appear shortly before, during, and after birth and during the weaning period.

In general, there is a distinction between the following time periods:

Segment I: Fertility and early embryonic development to detect drug-induced toxic effects before mating, through mating, and implantation (fertilized egg or zygote, prior to implantation, and prior to formation of the three primary germ layers). This includes changes in estrous cycle, tubular transport, determination of number of corpora lutea and implantation sites, live and dead conceptuses, etc.

Segment II: The embryo–fetal development studies (embryo during major organ development, i.e., organogenesis, malformations, fetal growth and functional deficits, and postembryonic period).

Segment III: The prenatal and postnatal development (neonate or postnatal offspring) including maternal function such as gestation or lactation through weaning. On the other hand, such effects may appear late in development and therefore observations are continued through sexual maturity. Females are allowed to deliver and rear offspring to weaning at which time one male and one female offspring per litter should be selected for rearing to adulthood and mating to assess reproductive competence. The most important investigations are: necropsy of all adults, histological evaluation of all organs with macroscopic findings, live offspring at birth, dead offspring at birth, body weight at birth, peri- and

postweaning survival, physical development, sensory functions and development, and behaviour.

These segments can be tested separately or in a combined manner. All stages of development from conception to maturity and the detection of acute and delayed effects of exposure through one complete life cycle should be examined. The standard species are rodents, rats as the preferred rodent species for all study types, and the rabbit as the second nonrodent species for the embryo toxicity studies. Rarely, mice or monkeys are being used too if special conditions, usually kinetic data, justify such species. The route of administration should be similar to the intended human usage.

4.1.7. Preclinical Safety Evaluation of Biotechnology-Derived Products (ICH S6)

This guidance is applicable for recombinant DNA proteins, vaccines, peptides, plasma derived products, endogenous proteins extracted from human tissues, or oligonucleotide drugs, etc., while, e.g., heparin, vitamins, and cellular blood components are not covered.

For biotechnology products, high flexibility for the development is recommended and steps should be reconsidered on a case-by-case basis.

Usually, two species should be used, but when the biological activity is well understood or when in short-term toxicity studies the effects were similar in both species, then the long-term testing could be restricted to one species only. When no relevant species can be identified, then one should consider the use of homologous proteins or transgenic animals.

Recommended Types of Safety Studies *Safety Pharmacology*, i.e., testing of the vital function such as cardiovascular, respiratory, and central nerve system functions is recommended, but S6 mentions also renal function, which from today's viewpoint would not be necessary before first administration of a compound in humans.

Some information on *absorption*, *disposition*, and *clearance* in the animal models is desirable before clinical trials and systemic exposure of the compound should be monitored, as well as the appearance of antibodies and their ability to neutralize the intended effect.

The *immune response* could also alter the pharmacokinetic or -dynamic effects. Anaphylactic responses tested in the guinea pig is not predictive for humans and therefore not necessary. The same holds true for the standard testing batteries for immunotoxicity, these are not recommended.

Studies with a duration of two weeks up to three months are often sufficient and only with chronic use in humans six-months studies should be considered. Flexibility may allow a further reduction of the traditional testing program for the reproductive endpoints. Such studies may not be necessary if a new compound shows similar effects to related well-known compounds. The same holds true for genotoxicity studies: the standard studies are not appropriate but testing on a case-by-case basis of impurities or promoter studies might be helpful.

Long-term carcinogenicity studies are usually not appropriate, but when there is cause for concern then studies with a single rodent species are sufficient. A cause for concern may have appeared in general toxicity studies, or a stimulation of the growth of normal as well as malignant cells can be assumed.

4.1.8. Safety Pharmacology Studies for Human Pharmaceuticals (ICH S7A)

The guideline ICH S7A requires testing of the vital functions usually in single-dose studies with focus on the *Core Battery*:

- Investigation of the effects of a test substance on vital functions
  - Central nervous system
  - Cardiovascular system
  - Respiratory system
  - Other systems as appropriate
- Exclusion of a system or function should be justified

and additional assays when needed:

- Follow-up studies, which provide a greater depth of understanding or additional knowledge compared to those studies provided by the Core Battery (e.g., mechanistic studies)
- Supplemental studies, which evaluate effects of the test substance on systems which are not addressed by the Core Battery, when there

is cause for concern not addressed elsewhere (e.g., in toxicology)

Timing of Studies The Core Battery is usually required before the first administration to humans and follow-up or supplemental studies are required when supporting safety, e.g., during clinical development, to clarify observed or suspected undesirable effects in animals or humans. Before the approval, the effects on all organ systems, if not covered elsewhere (e.g., in toxicology), should be addressed.

Good Laboratory Practice (GLP) As in all safety studies, GLP should be applied to the Core Battery, while follow-up and supplemental studies should be conducted according to GLP as far as possible and deviation should be justified and their impact discussed. Primary and secondary pharmacodynamic studies need not to be conducted according to GLP.

Special focus is given to the cardiovascular system. According to ICH S7A, blood pressure, heart rate, and electrocardiograms should be assessed for the Core Battery. Further in vivo, in vitro, and/or ex vivo evaluations should be considered, including methods for repolarization and conductance abnormalities.

4.1.9. Nonclinical Studies for Assessing Risk of Repolarization-Associated Ventricular Tachyarrhythmia for Human Pharmaceuticals (ICH S7B)

This text was finalized at a time when the details of ICH S7B were not yet outlined. With the increase of awareness that noncardioactive drugs, used for sometimes nonlife threatening diseases, can cause QT prolongation and serious dysrhythmias such as Torsade de Pointes, there appeared the need for further precision. Accordingly, the ICH Expert Working Group created ICH/S7B.

The QT interval (time from the beginning of the QRS complex to the end of the T wave) of the electrocardiogram (ECG) is a measure of the duration of ventricular depolarization and repolarization.

QT interval prolongation can be congenital or acquired (e.g., pharmaceutical-induced). When the QT interval is prolonged, there is an increased risk of ventricular tachyarrhythmia, including Torsade de pointes, particularly when combined with other risk factors (e.g., hypokalemia, structural heart disease, bradycardia. To cope with these issues, a relatively flexible approach is given with the ICH S7B nonclinical testing strategy as seen in Figure 1.

Figure 1.

The basis for the integrated risk assessment are in vitro and in vivo assays, supported by any knowledge about the chemical/pharmaceutical class.This first risk assessment may later be modified when results from follow-up studies or relevant nonclinical or clinical information become available. The evidence of risk summarizes the preclinical evaluation of the proarrhythmic potential for the clinicians.

In parallel with the development of ICH S7B, a clinical guideline (ICH E14) was drafted and reached Step 4 also in 2005. During the discussion between these two expert groups, the question was often raised whether toxicologists could exclude any risk for QT prolongation for humans with their testing strategies. Of course, they cannot because clinicians cannot exclude any of these risks for future patient generations based on their clinical trial results only. In addition, the FDA is currently comparing preclinical data with clinical results and a few cases could be identified already where QT prolongation was observed under clinical conditions while the preclinical tests were negative. This discrepancy is the basis for the diplomatic text in regard to the need for availability of S7B QT studies:

- Timing of S7B Non-Clinical Studies and Integrated Risk Assessment in Relation to Clin-

ical Development / Step 4, June 2005, Brussels: Conduct of S7B non-clinical studies assessing the risk for delayed ventricular repolarization and QT interval prolongation prior to first administration in humans should be considered.

- These results, as part of an integrated risk assessment, can support the planning and interpretation of subsequent clinical studies.

The term "should be considered" opens all flexibility to carry out the studies before it is done for the first time in humans or at a later stage of development. In practice, in most cases these studies are available before IND, because the industry wants to provide best safety to volunteers and patients. However, in conclusion is has to be stated that ICH/S7B proposes a series of nonclinical tests which are believed to predict the potential that a compound may prolong cardiac repolarization in vivo, in animals, and in humans.

Currently, these data have little impact on the clinical development proposals which are included in the draft guideline E14.

4.1.10. Immunotoxicology Studies (ICH S8)

The guideline ICH S8 is restricted to unintended immunosuppression and immunoenhancement, excluding allergenicity or drug-specific autoimmunity. The guideline applies to new pharmaceuticals intended for use in humans as well as to marketed drug products proposed for different indications or other variations on the current product label, but does not apply to biotechnology-derived pharmaceutical products covered by ICH S6 and other biological pharmaceuticals.

Immunosuppression or -enhancement can be associated with two distinct groups: 1) drugs intended to modulate immune function for therapeutic purposes (e.g., to prevent organ transplant rejection) where adverse immunosuppression can be considered exaggerated pharmacodynamics and 2) drugs not intended to affect immune function but cause immunotoxicity due to, for instance, necrosis or apoptosis of immune cells or interaction with cellular receptors shared by both target tissues and nontarget immune system cells. All new human pharmaceuticals should be evaluated for the potential to produce immunotoxicity.

Methods include standard toxicity studies (STS) and additional immunotoxicity studies conducted as appropriate. Whether additional immunotoxicity studies are appropriate should be determined by a weight-of-evidence review of cause(s) for concern. The immunotoxicity evaluation follows a straight-forward strategy which is detailed in Figure 2 and 3.

Figure 2.

The assessment of immunotoxicity should include the statistical and biological significance of the changes, the severity of the effects, dose–exposure relationship, a safety factor above the expected clinical dose, treatment duration, number of species and endpoints affected, and changes that may occur secondarily to other factors (e.g., stress), etc.

Additional immunotoxicity testing should be considered:

- If the pharmacological properties of a test compound indicate the potential to affect immune function (e.g. anti-inflammatory drugs).

- If the majority of the patient population for whom the drug is intended is immune-compromised by a disease state or concurrent therapy.
- If a compound is structurally similar to compounds with known immunosuppressive properties.
- If the compound and/or its metabolites are retained at high concentrations in cells of the immune system.
- If clinical findings are suggestive of immunotoxicity in patients exposed to the drug.

Figure 3.

If the weight-of-evidence review indicates that additional immunotoxicity studies are needed, then there are a number of assays which can be used, such as a T-cell dependent antibody response (TDAR). If specific cell types are affected in STS not involving cells participating in a TDAR, assays that measure function of that specific cell type might be conducted. Immunophenotyping of leukocyte populations, a nonfunctional assay, may be conducted to identify the specific cell populations affected and may provide useful clinical biomarkers.

Studies with 28 consecutive daily doses in rodents are generally accepted. Adaptations of immunotoxicity assays have been described using nonrodent species. The species, strain, dose, duration, and route of administration used in immune function assays should be consistent with the nonclinical toxicology study in which an adverse immune effect was observed.

Usually both sexes should be used in these studies, excluding nonhuman primates. The high dose should be above the No Observed Adverse Effect Level (NOAEL) but below a level inducing changes secondary to stress. Multiple-dose levels are recommended in order to determine dose–response relationships and the dose at which no immunotoxicity is observed.

Additional studies may show that no risk of immunotoxicity can be detected and no further testing is needed.

Additional studies may demonstrate a risk of immunotoxicity but there is not sufficient data to make a reasonable risk–benefit decision. In this case, further testing may be of benefit, which provides sufficient information for the risk–benefit decision. If the overall risk–benefit analysis suggests that the risk of immunotoxicity is considered acceptable and/or can be addressed in a risk management plan, then no further testing in animals might be called for.

If the weight-of-evidence review indicates the need for additional immunotoxicity studies, these should be completed before exposure of a large population of patients, usually Phase III. If the target patient population is immunocompromized, immunotoxicity testing can be initiated at an earlier time point in the development of the drug.

The different methods which are recommended for the evaluation of immunotoxic effects are summarized as follows.

Standard toxicity studies are:

Hematology	total leukocyte counts and absolute differential leukocyte counts
Clinical chemistry	globulin levels and A/G ratios
Gross pathology	lymphoid organs/tissues
Organ weights	thymus, spleen, (optional: lymph nodes)
Histology	thymus, spleen, draining lymph node, and at least one additional lymph node, bone marrow, Peyer's patch* , NALT**, BALT**

* Oral administration only.
** Inhalation administration only

Additional immunotoxicity studies are:

- T-cell dependent antibody response (TDAR)
- Immunophenotyping (lymphocyte subsets)
- Natural killer cell activity assays
- Host resistance studies
- Macrophage/neutrophil function
- Assays to measure cell-mediated immunity

This new ICH guideline replaces all guidelines from EU, USA, and Japan. It represents a very pragmatic approach and uses studies, e.g., standard toxicity studies, which are conducted anyhow. There is high confidence in the prediction of these assays for any potential of new compounds to induce immune suppression or stimulation. This guideline helps to reduce the number of animals and requires additional studies only in special cases for concern.

4.1.11. Nonclinical Safety Studies for the Conduct of Human Clinical Trials for Pharmaceuticals (ICH M3)

ICH M3 provides information which studies and of which duration are needed before the different clinical phases of development can be started. In addition to this timing of preclinical studies in dependence of clinical development plans, there are recommendations under which conditions different population can be included into clinical trials, populations such as men, women of childbearing potential or pregnant women, and finally pediatric populations.

The objectives of M3 are: To reduce differences between regions; to facilitate timely conduct of clinical trials; to reduce unnecessary use of animals and other resources; to promote early availability of new drugs. This guidance was implemented because regulatory recommendations differed among regions of Europe, USA, and Japan. Would it be possible to develop a mutually acceptable guidance?

The guidelines provide general guidance for drug development. A guideline is not a legal requirement. Approaches should be scientifically and ethically appropriate. The different endpoints are addressed in detail in this note.

Study requirements before the first starting dose in humans are:

- Safety pharmacology studies
- Kinetic/exposure data
- Single- and repeat-dose studies
- Local-tolerance studies
- Genotoxicity studies (in vitro)
- Phototoxicity studies

The requirement for the Core Battery of **safety pharmacology** is described in Section 4.1.9.

For **kinetics**, an information on exposure data (AUC) in animals prior human clinical trials is needed, while ADME data are needed at completion of phase I (human pharmacology) studies.

The duration for **repeat-dose toxicity studies** is related to the duration of clinical trials and their therapeutic indication. In principle, the duration of animal studies is equal to or exceeds the duration of the human clinical trials. In general, there is a relationship of 1:1 for studies in two mammalian species (one nonrodent). The details can be found in Table 8.

Table 8. Duration of repeated-dose toxicity studies to support Phase III trials in the EU*

Duration of clinical trials dose	Minimum duration of repeated toxicity studies	
	rodent	nonrodents
Up to 2 weeks	1 month	1 month
up to 1 month	3 months	3 months
up to 3 months	6 months	6 months
$>$ 3 months	6 months	6–12 months

* This table reflects the marketing recommendations in the three regions except a chronic nonrodent study is recommended for clinical use $>$ 3 months.

This table was updated by thorough additional Japanese studies in 2000 during the fifths ICH conference in San Diego, USA. The Japanese scientists compared the utility of routine four-week toxicity studies with two-week studies and concluded that in regard to the prediction of toxicities to the male reproductive organs two-week studies were as valid as four-week studies, therefore the former regional Japanese requirement to ask for a minimum duration of four-week studies before starting trials in men was dropped for a global consensus that the minimum duration of nonclinical studies is two weeks in rodents and two weeks in nonrodents.

On the other hand, regional differences continue in regard to **single-dose studies** in animals supporting single-dose studies in humans: In the United States, single-dose toxicity studies with extended examinations can support single-dose human trials. This concept encouraged the EU to offer comparable options with the microdosing

concept. This principle may especially be valuable for gaining on kinetic data very early for go/no go decisions, when several candidates are being developed in parallel.

Results from two in vitro **genotoxicity** studies are recommended to be available prior to first administration to humans, while the standard battery should be completed prior the initiation of phase II studies.

Carcinogenicity studies do not need to be completed in advance of the conduct of clinical trials unless there is cause for concern (ICH/S1A). For pharmaceuticals to treat certain serious diseases, carcinogenicity testing, if needed, may be concluded post-approval.

4.1.12. Inclusion of special populations (ICH M3)

For the inclusion of different patient populations, there exist regional differences, especially for **women with childbearing potential**:

- High level of concern for unintentional exposure of the embryo/fetus
- Currently regional differences in the timing of reproduction toxicity studies to support the inclusion
  Japan: assessment of female fertility and embryo fetal development should be completed prior to the inclusion of women of childbearing potential using birth control in any type of clinical trial
  EU: assessment of embryo fetal development should be completed prior to Phase I trials in women and female fertility studies prior to phase III trials
  US: women of childbearing potential may be included in early, carefully monitored studies without reproduction toxicity studies, provided appropriate precautions are taken to minimize risks
  US: assessment of female fertility and embryo fetal development should be completed before phase III trials

The inclusion of children into clinical trials has gained further tremendous interest:

- Safety data from previous adult human exposure:
  Most relevant information
  Necessary before pediatric clinical trials
- Prior trials:
  Appropriate repeated-dose toxicity studies
  All reproduction toxicity studies
  Standard battery of genotoxicity tests
  Juvenile animal studies should be considered
- Carcinogenicity testing:
  Prior to long-term exposure of children
  Cause for concern

4.1.13. The Common Technical Document (ICH M4)

The Common Technical Document (CTD, ICH M4) is another very important multidisciplinary guideline, which combines information for the three disciplines within the ICH process: for quality, safety, and efficacy. The following illustration focuses predominantly on the preclinical safety issues (Figure 4). For detailed information on the other aspects and the general organization, see Sections 4.2 and 4.3.

The objectives of M4 are to assist authors in the preparation of nonclinical pharmacology, pharmacokinetics, and toxicology written summaries in an acceptable format. The CTD is not intended to indicate what studies are required, but provides an appropriate format for the nonclinical data. The CTD is nothing else than a placeholder for the different parts of a documentation for the market authorization process.

No guideline can cover all eventualities; common sense and a clear focus on needs of regulatory authority assessor are the best guides to constructing an acceptable document. Therefore, modify the format if needed with the aim to provide the best possible presentation and facilitate the understanding for the evaluation of the results.

The **Nonclinical Summary** is organized as follows:

1) Pharmacology
   a) Written Summary
   b) Tabulated Summary
2) Pharmacokinetics
   Written Summary
   Tabulated Summary
3) Toxicology
   Written Summary
   Tabulated Summary

Figure 4.

This organization is kept up in all parts of the dossier, it is repeated for the overview, the summaries and the reports.

Details are:

1.a. Pharmacology, Written Summary
- Brief Summary
- Primary Pharmacodynamics
- Secondary Pharmacodynamics
- Safety Pharmacology
- Pharmacodynamic Drug Interactions
- Discussion and Conclusions

3.a. Toxicology: Written Summary
- Brief Summary
- Single-Dose Toxicity
- Repeat-Dose Toxicity
- Genotoxicity
- Carcinogenicity
- Reproduction Toxicity Local Tolerance
- Other Toxicity Studies
- Discussion and Conclusions

The kinetic information should be integrated across studies and across species, exposure in the test animals should be related to exposure in humans given the maximum intended doses.

In vitro studies should precede in vivo studies. Where multiple studies of the same type need to be summarized within the Pharmacokinetics and Toxicology sections, studies should be ordered by species, by route, and then by duration (shortest duration first).

Species should be ordered as follows:

1) Mouse
2) Rat
3) Hamster
4) Other rodent
5) Rabbit
6) Dog
7) Nonhuman primate
8) Other nonrodent mammal
9) Nonmammals

It is also recommended to limit the information in the summaries and overview: The overview should contain the essential and critical results on approximately 30 pages. The length of the nonclinical Written Summaries in general should not exceed 100-150 pages. The Brief Summaries for pharmacology should be written on two to three pages, for pharmacokinetics also two to three pages and for toxicology approximately six pages.

The **repeat-dose toxicity** studies (including supportive toxicokinetics evaluation) should be

summarized in order by species, by route, and by duration, a brief detail of the methodology is needed, the important findings (e.g., nature and severity of target organ toxicity, dose (exposure)/response relationships, no observed adverse effect levels, etc.) should be highlighted. The nonpivotal studies can be summarized in less detail (pivotal studies are the definitive GLP studies specified by ICH M3).

For the **carcinogenicity** studies (including supportive toxicokinetics), a brief rationale should explain why the studies were chosen and what is the basis for high-dose selection. Individual studies should be summarized in the following order: Long-term studies (in order by species; including range-finding studies that cannot appropriately be included under repeat-dose toxicity or pharmacokinetics), then short- or medium-term studies (including range-finding studies that cannot appropriately be included under repeat-dose toxicity or pharmacokinetics). Other studies such as antigenicity, immunotoxicity, mechanistic studies (if not reported elsewhere), dependence, studies on metabolites, studies on impurities or other studies should be summarized.

Module 2 contains in addition 34 templates and 31 examples. The examples have been taken from real dossiers and give good orientation how to fill out the templates. Module 4 finally contains all nonclinical study reports and is organized in an granular manner with the same principles for all types of compounds and studies.

This CTD has been tested in practice for a couple of years. Although not perfect for every case, it has proven its usefulness. Industry knows where to place specific information and data and regulators know where to find them. This has facilitated the review process tremendously, only one dossier is necessary for international registration, a lot of resources can be diverted to more important issues.

But the CTD is a living document, its weaknesses are apparent. In order to improve its quality and practicability, suggestions and proposals for improvements are invited from the public. These modifications are being dealt with within the process of "questions and answers", the ICH experts will continue to publish repeatedly their conclusions.

4.2. Clinical Trials

Before broad application of any treatment to patients suffering from a particular disease, the reliable efficacy and safety of the treatment needs to be demonstrated. As single-case studies and retrospective comparison of effects are not suitable to predict the success of a treatment in future patients, prospective, controlled, randomized, blinded and well-documented clinical trials are the worldwide recognized, scientific approach to achieve marketing authorization and clinical acceptance.

A clinical trial is any investigation in human subjects intended to discover or verify the clinical, pharmacological, and/or other pharmacodynamic effects of one or more medicinal products, medical devices or treatment procedures and/or to identify any adverse reactions to these treatments and/or to study absorption, distribution, metabolism, excretion or interaction of these treatments with the object of ascertaining its (their) safety and/or efficacy.

Methodology and quality standards of clinical trials have been rapidly developed in the last 50 years. The planning, performance and supervision of clinical trials are highly regulated on national and international levels. Scientific guidelines for the development program of drugs and the designs of required clinical trials in particular indications, released by the European and American health authorities, define the state-of-the-art and their recommendations should be followed. The protection, safety, and integrity of patients and healthy subjects participating in clinical trials are guaranteed through review and approval of each clinical trial by health authorities and independent ethics committees as well as by extensive subject data protection, information and consent requirements.

Especially the development of a new drug (Investigational Medicinal Product or IMP) requires the generation of in depth pharmaceutical, pharmacological, preclinical and clinical information within a development plan. The results of the different trials have to be compiled and presented in a dossier in an internationally accepted order and submitted to the respective health authorities for detailed review and evaluation of efficacy and safety of the IMP before a marketing authorization for use of the IMP in defined indications, dosage and conditions of use

is granted. Also after introduction to the market, safety and efficacy are further observed and evaluated in specially designed clinical trials or non-interventional trials.

1) Medical and ethical justification of the trial
2) Information of the human subject participating on the risk involved
3) His or her freely given consent (informed consent)

Thus, the goal of the special legal requirements is the protection of the human subject. Special parts of the U.S. Code of Federal Regulations (CFR) have been devoted to this aim, Part 50, Protection of Human Subjects (http://www.access.gpo.gov/nara/cfr/-waisidx_06/21cfr50_06.html) and Part 312, Investigational New Drug Application (http://-www.access.gpo.gov/nara/cfr/waisidx_06/-21cfr312_06.html). Basic elements of informed consent are designed to guarantee a free and self-responsible decision of the trial subject. This involves a statement that the study involves research, an explanation of the purpose of the research, and the expected duration of the subject's participation. A description of benefits and any reasonably foreseeable risks or discomforts must be given to the subject. Benefits obviously do not exist for trials in voluntary healthy subjects. The subject must be informed of appropriate alternative procedures or courses of treatment, especially if these might be to his or her advantage. Existing confidentiality and exceptions thereto also have to be described; an exception, for example, is that the records may be inspected by the competent authority. Furthermore information on possible financial compensation in case of injury or medical treatment must be provided. The fact that participation in the trial is voluntary and that the subject can refuse to participate without penalty must be included in the information.

Further elements pertaining to informed consent may include information on currently unforeseeable risks, on possible termination of the investigation, and the consequences of a subject's decision to withdraw from the trial. The patients should be notified of the number of subjects participating in the trial and also of significant new findings to let them decide whether or not to continue their participation. The subject must give written consent to participation in the trial.

Before the investigator is allowed to start a clinical trial, an application has to be approved by the competent authority. In the EU, the requirements are listed in Directive 2001/20/EC (http://ec.europa.eu/enterprise/-pharmaceuticals/eudralex/vol-1/dir_2001_20/-dir_2001_20_en.pdf). In the US, the sponsor of an investigation has to submit an *Investigational New Drug Application* (IND) to the FDA, if a clinical investigation is to be conducted with a new drug. Unless the FDA notifies the sponsor of any objections, IND goes into effect and the trial may be started thirty days after the FDA has received the IND.

A written positive opinion of an *Ethical Committee* has to be received by the sponsor before the trial can commence. In the United States, the ethical committee is called the *Institutional Review Board* (IRB), 21 CFR Part 56 (http://-www.access.gpo.gov/nara/cfr/waisidx_06/-21cfr56_06.html). The respective regulations describe the general standards for the composition, operation, and responsibility of an IRB that reviews clinical investigations. The term IRB denotes any board, committee, or other group formally designated by an institution to review, to approve the initiation of, and to conduct periodic review of biomedical research involving subjects. The primary purpose of such a review is to assure the protection of the rights and welfare of the human subjects. Clinical investigations relating to new drugs can only be initiated after the investigation has been reviewed by, approved by, and remains subject to continuing review by an IRB. An IRB has to have at least five members with varying professional backgrounds necessary to review specific research activities. The persons must be knowledgeable in these areas. No IRB may consist entirely of men or women or entirely of members of one profession. One member has to work in a lay area (e.g., lawyer, ethicist, member of the clergy). One member of the IRB is not to be affiliated with the institution whereas the other members may belong to the institution. No IRB member may have a conflicting interest in the research project (e.g., because the IRB member is also an investigator).

The IRB has to approve, require modification of, or disapprove all research activities covered

by the investigation. The Informed Consent of the participant in the trial is subject to inspection by IRB. The criteria for IRB approval of research are contained in 21 CFR Part 56.111 (http://a257.g.akamaitech.net/7/257/2422/-10apr20061500/edocket.access.gpo.gov/-cfr_2006/aprqtr/pdf/21cfr56.111.pdf). The institution responsible for the trial or the IRB must prepare and maintain adequate documentation of IRB activities. The parent institution is presumed to be responsible for the operation of an IRB.

4.2.1. Phases of Clinical Drug Development

The generation of information in the development of a new drug occurs in four phases:

Phase I	Human pharmacological trials
Phase II	Tolerability and dose finding trials
Phase III	Proof of efficacy and safety
Marketing authorization	
Phase IV	Evaluation of long-term safety and efficacy in the indication(s) and patient population(s) for which the drug received a marketing authorization

Theoretically, the phases are performed in consecutive order. However, the development of each drug requires a specific plan with different types and numbers of trials based on the results of the preclinical and earlier trials. Thus, the phases can overlap, be combined, or further divided, e.g., into Phase Ia, Ib, IIa, IIb, III, and IIIb, which indicates the types of trials considered belonging to the earlier or later stage of a particular Phase. Human pharmacological trials are mostly performed in Phase I but often in addition along Phase II, III, and IV.

Phase I The human pharmacological investigation of new drugs in small subject populations under strictly controlled conditions in specialized Phase I units is an efficient way to explore the suitability of a new drug for human use in general and to detect the potential for efficacy of the drug in the envisaged indication. Different types of trials are conducted:

- The first administration of a new drug to man and the evaluation of the pharmacological properties of a new drug are mostly performed in healthy male volunteers. Healthy female volunteers can only be included once the required reproductive toxicology tests have been performed. For safety reasons, drugs with a potential for cell damage such as anticancer drugs or for a specific immune response can only be tested in patients with the respective disease.
  Beginning with doses well below the no-effect level in animals and the expected effective dose range in humans, groups of 3 to 8 subjects get exposed to increasing single doses and placebo until the maximum tolerated dose level (MTD) is reached. This is followed by exploration of the MTD under multiple dosing in comparison to placebo.
- With a dose in the tolerability range, the pharmacological properties of the drug such as extent of absorption, distribution in the body, ways of metabolization, as well as route and extent of excretion (ADME trials) are investigated in 3 to 4 subjects after single-dose administration of radio-labeled drug in authorized institutions.
- The pharmacokinetic behavior for different potential dosage forms (e.g., infusion, oral solution, fast- and/or slow-release tablet, etc.) is compared in absolute (intravenous versus oral formulation) or relative (oral solution versus oral formulation) "bioavailability studies".
- To explore potential differences in the pharmacokinetic profile between healthy young and healthy elderly subjects (65 years and older) a parallel-groups trial with single- or multiple-dose administration of the drug to those two populations is performed with drugs indicated for these age groups.
- "Bioequivalence studies" are performed with the same type of formulation to compare, e.g., the pharmacokinetic behavior under fasting and fed conditions or to compare the formulations from two different manufacturing sources.
  Highly sensitive and specific analytical methods for the mother compound and its active metabolite(s) are used in these different types of pharmacokinetic trials to determine the drug levels over time in body fluids such as blood (plasma or serum), urine, or saliva. Comparing the pharmacokinetic conditions intra-individually by performing trials with randomized cross-over designs as well as the use of sophisticated biostatistical methods for

the calculation of results and their extrapolation allow to gain reliable information on the drug with small populations of 8 to 24 subjects per group.

- Depending on the enzymatic pathway of metabolization of the drug, the pharmacokinetic behavior of the drug in subjects with different pharmacogenetic and genotype conditions ("fast and slow metabolizers") are performed, especially to predict the potential for decreased tolerability of the drug in patients with slow metabolization capacity resulting in accumulation of the drug in the body after multiple administration.
- Drugs with an excretion predominantly via the kidney *or* the liver have the potential for accumulation in patients with renal or liver insufficiency. Evaluation of the pharmacokinetic behavior in patients with a different degree of renal or liver insufficiency is performed by comparing their drug plasma or serum levels with those in healthy subjects.
- In an attempt to predict efficacy of the drug or particular dose levels in patients, trials using special validated pharmacodynamic and psychometric methods or models, and comparing the effects of the drug with those of placebo administration, are also performed in healthy volunteers in Phase I.
- As many patients have to take different drugs for the same disease or for different diseases in parallel, a potential pharmacokinetic or pharmacodynamic interaction of the new drug with a selection of other drugs has to be investigated in "interaction studies".

Usually, 200 to 500 subjects are enrolled in Phase I trials for the development of a new drug.

Phase II. In Phase II, the new drug is administered for the first time to patients suffering from the disease intended to be treated. The objectives of clinical trials in this phase are to obtain information on

- efficacy in comparison to placebo
- therapeutic dose range
- optimal dose and dosing scheme
- dose–response relationship
- short-term tolerability
- short-term safety

The trials are performed in selected patients fulfilling narrow in- and exclusion criteria, with treatment duration of only few days to 6 weeks and under strong medical supervision in specialized hospitals. A larger number of diagnostic tests and patient visits than under normal treatment conditions are required.

The following types of trials are performed:

- A first administration of a new drug to patients with the respective disease is often performed in a pilot trial with 8 to 20 highly selected patients, in which the drug is administered unblinded, as a single dose or for a very short period of time, and under very controlled conditions, to get an impression of the tolerability of the drug in patients with the respective pathological condition.
- Proof-of-Concept trials (Phase IIa), ideally investigating the drug and placebo effects by intra- and inter-individual comparisons, using a double-blind, randomized cross-over design if the disease condition is such that the preconditions for all treatment periods are comparable. Mostly, however, these trials are performed in parallel groups with different dose levels (including expected no-effect dose, optimal dose and maximum-effect dose) investigating the inter-individual differences to placebo and sometimes to a standard treatment, double-blind, randomized and – if necessary – with a dose titration period at the beginning. Usually 40 to 100 patients per treatment arm are required to show statistically significant differences between the treatments. This sample size depends on the variability of the chosen efficacy parameters, the placebo responder rate in this particular indication and the efficacy of the new drug. Special emphasis is put on the evaluation of tolerability and safety of the different treatments. Due to the relatively short duration of the treatment and the fact that the patients may receive an insufficient dose level or placebo, the benefit for patients in these trials is limited.
- Comparative trials (Phase IIb) are also performed in patients with well-defined disease conditions and without concomitant other diseases. The trials are mostly performed double-blind, randomized, in parallel groups, comparing selected dose levels of the new drug with established drugs in this indication, sometimes also including placebo. Dif-

ferent dosing conditions, different diagnostic parameters and different efficacy parameters are included into the study designs of trials in that phase. The tolerability and safety of the different treatments is also compared.

All-together, the number of patients in Phase II does not exceed a few hundred.

Phase III. The purpose of Phase III is to investigate the new drug under conditions as close as possible to the daily life situation of patients. The exclusion criteria are less stringent, defined concomitant diseases and treatments are permitted, the treatment duration is according to the need of the disease. The number of test parameters and of the trial-requested patient visits is reduced. However, the studies are again performed under controlled, double-blind, randomized conditions. But 100 patients or more are invited to continue their trial with an open, uncontrolled extension for up to one year.

The objectives of this phase are

- to identify and demonstrate superiority of the new drug over existing comparators or to establish comparability with existing treatments
- to confirm the optimal dose
- to prove efficacy and tolerability for a treatment duration adequate for the disease
- to establish the safety profile of the new drug and to identify relatively rare adverse drug reactions
- to substantially increase the information available for estimating the risk–benefit as well as cost–benefit ratio of the new treatment in comparison to existing treatments
- to investigate special questions like interaction with other drugs or impact of different conditions such as age, impaired renal or liver function on safety, and efficacy of the drug
- to investigate the new drug in special populations

The clinical trials in Phase III include several hundred patients, when the primary efficacy parameter is prevention of the disease, then even thousands of patients are enrolled. These trials are performed in many different hospitals or practices, often in different countries or even globally. Standardization of trial conditions, assessments, and documentation are a logistic challenge but vital for the chance to show statistically significant differences between the treatments.

Phase III trials performed before and their results included in the marketing authorization application dossier are defined as belonging to Phase IIIa; trials performed after submission but before granting the marketing authorization are defined as Phase IIIb. The objectives of these trials are generation of additional information potentially required by the competent authorities before granting the marketing authorization, to collect more safety information and to generate interest for the new drug in the investigator community.

Phase IV. The purpose of Phase IV is to investigate the safety of the drug and efficacy under normal clinical conditions in patients with the respective indication, to collect broad safety information or pharmacoeconomic and epidemiological data. The trials have either short protocols with requirements for minimal additional diagnostic activities to normal procedures and with nearly no exclusion criteria or they are purely observational, so-called "Non-interventional trials", defined as follows:

"A study where the medicinal product(s) is (are) prescribed in the usual manner in accordance with the terms of the marketing authorization. The assignment of the patient to a particular therapeutic strategy is not decided in advance by a trial protocol but falls within current practice and the prescription of the medicine is clearly separated from the decision to include the patient into the study. No additional diagnostic or monitoring procedures are applied to the patients and epidemiological methods are used for the analysis of collected data."

For these trials, no authorization from the health authorities is required. The number of patients included in Phase IV is unlimited. Phase IV begins with granting of the marketing authorization and ends with the discontinuation of sales.

Another approach to classifying clinical trials is presented in a guideline of the EMEA entitled "General Considerations for Clinical Trials":

4.2.2. Methods for Proving Effectiveness

As with all scientific experiments, clinical trials should provide generally valid evidence from a limited number of observations. The reproducibility of a result can be determined after repetition of the test and the probability of general validity can be calculated with statistical methods. Clinical trials must therefore be designed and evaluated on the basis of biostatistical criteria.

The most reliable way of providing evidence of efficacy and safety is the performance of a confirmatory trial - mostly performed in Phase III. In such trial, the key hypothesis of interest follows directly from the primary objective of the trial, is always pre-defined, and is the hypothesis that is subsequently tested when the trial is complete. It is equally important to estimate with due precision the size of the effects attributable to the treatment of interest and to relate these effects to their clinical significance.

In such trial, unavoidable changes are explained and documented, and their effect is examined. A justification of the design of such trial, and of other important statistical aspects such as the principal features of the planned analysis, is set out in the protocol. Only a limited number of key clinical questions relevant to efficacy or safety are allowed to be addressed and can be answered. A single primary variable should be selected.

In contrast to confirmatory trials, exploratory trials – mostly performed in early drug development phases - have objectives which may not always lead to simple tests of predefined hypotheses, however, they may also be clear and precise. In addition, exploratory trials require sometimes a more flexible approach to design so that changes can be made in response to accumulating results. Their analysis may entail data exploration; tests of hypothesis may be carried out, but the choice of hypothesis may be data-dependent. Such trial cannot be the basis of the formal poof of efficacy, but may contribute to the total body of relevant evidence.

Any individual trial may have both confirmatory and exploratory aspects as in most confirmatory trials the data are also subject to exploratory analyses which serve as a basis for explaining or supporting their findings and for suggesting further hypotheses for later research.

An important element of a successful trial is the right selection of subjects. In the earlier phases, the choice of subjects is heavily influenced by the wish to maximize the chance of observing specific clinical effects of interest. Therefore, the protocol defines a narrow subgroup of the respective total patient population through the inclusion criteria and eliminates patients with potentially interfering factors and risk factors through the exclusion criteria. Structural uniformity can be further increased by stratification of each subject group according to certain characteristics like age range, sex or degree of illness of the subjects. However, by the time confirmatory trials are performed the trial population should more closely mirror the target population while maintaining sufficient homogeneity to permit precise estimation of the treatment effects.

To increase the comparability of the treatment groups and to avoid bias, the subjects must be assigned to the different treatment groups according to a randomization list. Preferably, this list should consist of randomization blocks to improve the chance that treatment groups will be of equal size.

Another technique to avoid bias in a clinical trial is *blinding*. In a single-blind trial the subjects are not informed about the treatment they receive, however, the investigator is aware of the type of treatment administered. In a double-blind trial the assignment of the patient to the treatment groups remains also unknown to the investigator. Precondition for a double-blind trial is the preparation of identically looking and tasting formulations for the test and the reference product. If this is technically not possible, the "double dummy technique" has to be applied: for test and reference medication an identically looking placebo version has to be prepared. The subjects get either the active version from the test medication plus the inactive version from the reference medication or vice versa, depending on their randomization assignment. Also the labeling of the blinded trial medication does not reveal which type of treatment is in which box. Individual sealed envelopes with the description of the trial medication for each subject are deposited with the investigator and can be opened in the case of occurrence of a serious adverse event in which the medically required action is dependent on the trial medication received.

The choice of the most suitable study design is depending on the objective of the trial and the conditions of the disease. Group (inter-individual) comparison (parallel design) can be used to in most medical conditions and is suitable for determination of optimal doses and comparison of efficacy. However, this design requires large patient numbers, especially if the efficacy parameters have a high variability or if small differences have to be identified.

Variability and thus the number of observations can be significantly reduced if the study is conducted as an intra-individual comparison (cross-over design) in the same subject. Each subject receives each of the test preparations in a random order with a sufficiently long wash-out phase between the periods. In pharmacokinetic trials in healthy subjects this design is mostly used, however, in patients it can only be applied in chronic illnesses with stable characteristics and when the termination of the first trial medication leads to a rapid reestablishment of the disease conditions before the start of the second treatment period. If this is not ensured, when the effect of one therapy continues into the subsequent treatment period (carry-over effect), the comparability of the two treatments is not given.

4.2.3. Adverse Drug Reactions

Despite state-of-the-art performed drug development, the efficacy of a medication in an individual patient cannot be guaranteed. On the other hand, already Paracelsus defined in the early 16th century that each drug has the potential of being a poison – depending on the dose administered. Therefore, physician and patient need to decide whether the relevance of the potential benefit of taking the medication outweighs the potential risk. With the increase of the seriousness of the disease and/or the impact of the symptoms on the patient's quality of life, patients are more willing to accept adverse drug reactions.

Participating in a clinical trial does not only contain the risk inherent in the medications administered but also the trial activities like blood withdrawals etc. include a certain risk for the subject to be harmed. For the evaluation of the safety profile of a drug administered in a clinical trial, it is very important to find out whether the occurrence of a negative experience is related to the study medication or not. Different terms have therefore to be distinguished:

"Adverse Event" (AE)	any untoward medical occurrence in a patient or clinical trial subject administered a medicinal product and which does not necessarily have a causal relationship with the treatment
"Adverse Drug Reaction" (ADR)	all untoward and unintended responses to an investigational medicinal product related to any dose administered
"Serious Adverse Event" or "Serious Adverse Reaction" (SAE) or (SAR)	any untoward medical occurrence or effect at any dose results in death is life-threatening, requires hospitalization or prolongation of existing hospitalization, results in persistent or significant disability or incapacity, or is a congenital anomaly or birth defect
"Suspected Unexpected Serious Adverse Reaction" (SUSAR)	an adverse reaction, the nature or severity of which is not consistent with the applicable product information (e.g., investigator's brochure for an unauthorized investigational product or summary of product characteristics for an authorized product) and which is suspected to be unexpected

An investigator is obliged to report every SAE within 24 hours to the sponsor of the clinical trial. In clinical trials performed outside the European Union, the sponsor is obliged to report all SAEs within 15 days, in case of life-threatening SAEs or death within 7 days, to the relevant health authorities and ethics committees. In European studies, only SUSARs need to be reported by the sponsor within these delays. In European trials the national health authority of the country where the sponsor of the trial is located is responsible for entering the information into the clinical trials section of the European safety database EudraVigilance. Also all investigators need to be informed by the sponsor about all SUSARs occurred with the drug.

According to internationally accepted standards, adverse events are classified according to the following categories:

"Intensity"	mild – moderate – severe
"Outcome"	resolved – resolving - not resolved - resolved with sequelae – fatal – unknown
"Causality"	certain – probable/likely – possible – unlikely - not related - unassessable/unclassifiable

In addition, onset and duration of AEs as well as required countermeasures are reported and analyzed in the safety evaluation of a clinical trial.

In an Annual Safety Report all AEs, all SAEs, and in Europe all SUSARs occurred - in all clinical trials performed and ongoing - must be pre-

sented and analyzed by the sponsor of a trial and an update of the risk-benefit analysis must be performed to justify the further development of the drug.

4.2.4. Good Clinical Practice

The need for quality standards and the assurance of their maintenance has been accepted for drug production as well as for preclinical and clinical drug development and has been defined in guidelines such as Good Manufacturing Practice (GMP), Good Laboratory Practice (GLP), and Good Clinical Practice (GCP).

The International Conference on Harmonization (ICH), a collaboration process between health authorities from USA, Europe, and Japan and pharmaceutical industry from these three regions, aiming to harmonize the standards, prerequisits, procedures, and documentation for drug development in the three regions, has developed guidelines on many aspects of drug development. The ICH Guideline on Good Clinical Practice (ICH E6 GCP) was adopted in 1996 by all ICH parties and in the following years implemented in the legislation in these regions and most other countries in the world. It represents the international ethical and scientific quality standard for designing, conducting, recording, and reporting clinical trials in human subjects. Compliance with GCP provides assurance that the rights, safety and well-being of trial subjects are protected and that the results of the clinical trials are reliable. The guideline is to provide a unified standard for the three regions to facilitate the mutual acceptance of clinical data by the regulatory authorities in these jurisdictions.

The following principles were agreed in ICH GCP:

1) Clinical trials should be conducted in accordance with the ethical principles that have their origin in the Declaration of Helsinki, and that are consistent with GCP and the applicable regulatory requirement(s).
2) Before a trial is initiated, foreseeable risks and inconveniences should be weighed against the anticipated benefit for the individual trial subject and society. A trial should be initiated and continued only if the anticipated benefits justify the risks.
3) The rights, safety, and well-being of the trial subjects are the most important considerations and should prevail over interests of science and society.
4) The available nonclinical and clinical information on an investigational product should be adequate to support the proposed clinical trial.
5) Clinical trials should be scientifically sound, and described in a clear, detailed protocol.
6) A trial should be conducted in compliance with the protocol that has been received prior institutional review board (IRB)/independent ethics committee (IEC) approval/favorable opinion.
7) The medical care given to, and medical decisions made on behalf of, subjects should always be the responsibility of a qualified physician or, when appropriate, of a qualified dentist.
8) Each individual involved in conducting a trial should be qualified by education, training, and experience to perform his or her respective task(s).
9) Freely given informed consent should be obtained from every subject prior to clinical trial participation.
10) All clinical trial information should be recorded, handled, and stored in a way that allows its accurate reporting, interpretation, and verification.
11) The confidentiality of records that could identify subjects should be protected, respecting the privacy and confidentiality rules in accordance with the applicable regulatory requirement(s).
12) Investigational products should be manufactured, handled, and stored in accordance with applicable good manufacturing practice (GMP). They should be used in accordance with the approved protocol.
13) Systems with procedures that assure the quality of every aspect of the trial should be implemented.

The preparation and implementation of a quality assurance systems with standard Operating Procedures (SOP) defining the roles and responsibilities of all parties involved, the processes, procedures, and documentation required and the approach to supervision of adherence to these SOPs through auditors, ensure that these

principles are reliably followed. In addition, health authorities perform inspections during the performance of a clinical trial, during review of the marketing authorization application or after granting of a marketing authorization to ensure that these principles are rigorously followed.

The protection of trial subjects is a central element in GCP. The principles for physicians involved in biomedical research have been established in the Declaration of Helsinki, adopted by the World Medical Association in 1964 and amended several times until 2002. The WHO guidelines, CIOMS guidelines, and many national guidelines and legislations emphasize as well on the fundamental need for subject protection in biomedical research.

GCP requires the establishment of independent, multidisciplinary ethics committees/institutional review boards to ensure the rights of the research subject, especially also in case of involvement of vulnerable populations, and to safeguard the integrity of the subjects. The IEC/IRB has to review all the ethical aspects of the trial protocol and accompanying documents, especially concerning the rationale and objective of the trial, the benefit-risk assessment, the subject information and informed consent process, the suitability of investigator and site, the compensation of trial subjects and investigators as well as the insurance coverage in case of injury.

4.2.5. Clinical Application Dossier

An especially important achievement of the ICH process was the adoption of Topic ICH M4, the "Common Technical Document" in 2000. This guideline presents the agreed upon common format for the preparation of a well-structured application dossier for applications supposed to be submitted to regulatory authorities of the three regions. It is aiming to significantly reduce the time and resources needed to compile applications for registration of new drugs and to ease the preparation of electronic submissions. Regulatory reviews and communication with each other and the applicant are facilitated.

The CTD is organized in five modules. While *Module 1* – containing administrative information and prescribing information (Summary of Product Characteristics = SmPC) is supposed to be region-specific, the other four Modules are common for the three regions.

Module 2 contains the CTD Summaries (see also Section 4.1.13):

- CTD Table of Content
- CTD Introduction
- Quality Overall Summary
- Nonclinical Overview
- Clinical Overview
  - Product Development Rationale
  - Overview of Biopharmaceutics
  - Overview of Clinical Pharmacology
  - Overview of Efficacy
  - Overview of Safety
  - Benefits and Risks Conclusions
  - Literature References
- Nonclinical Written and Tabulated Summaries
  - Pharmacology
  - Pharmacokinetics
  - Toxicology
- Clinical Summary
  - Biopharmaceutic Studies and Associated Analytical Methods
  - Clinical Pharmacology Studies
  - Clinical Efficacy
  - Clinical Safety
  - Literature References
  - Synopses of Individual Studies

Module 3 presents the information on quality, *Module 4* contains the nonclinical study reports.

Module 5 presents the clinical study reports and related information:

- Table of Contents of Module 5
- Tabular Listing of All Clinical Studies
- Clinical Study Reports
- Literature References

Topic ICH M4E is the guideline on the clinical documentation within the CTD. It explains in detail the type of information and assessments requested in the different sections of the CTD.

In the meantime, the three regions have implemented the CTD format into their national legislations including the standards for the electronic version (Table 9).

Table 9. Approach to classifying clinical studies according to objectives

Type of Trial	Objective of Trial	Trial Examples
Human pharmacology	assess tolerance define/describe pharmacokinetics and pharmacodynamics explore drug metabolism estimate activity	dose-tolerance trials single and multiple dose pharmacokinetic or pharmacodynamic trials drug interaction trials
Therapeutic exploratory	explore use for the targeted indication estimate dosage for subsequent trials provide basis for confirmatory study designs, endpoints, methodologies	earliest trials of relatively short duration in well-defined narrow patient populations, using surrogate or pharmacological endpoints or clinical measures dose-response exploration trials
Therapeutic confirmatory	demonstrate/confirm efficacy establish safety profile provide an adequate basis for assessing benefit/risk relationship to support licensing establish dose-response relationship	adequate and well controlled trials to establish efficacy randomized, parallel dose-response trials clinical safety trials trials of mortality/morbidity outcomes large simple trials comparative trials
Therapeutic use	refine understanding of benefit/risk relationship in general or special populations and/or environments identify less common adverse reactions redefine dosing recommendations	comparative efficacy trials trials of mortality/morbidity outcomes trials of additional endpoints large simple trials pharmacoeconomic trials

4.3. Quality of Pharmaceutical Products

Quality cannot be tested into products; i.e., quality should be built in by design. Pharmaceutical companies develop a product and its manufacturing process to consistently deliver the intended performance of the product. The information and knowledge gained from pharmaceutical development studies and manufacturing experience provide scientific understanding to support the establishment of criteria for the release of the products in line with current quality standards. An agreement on what is regarded as a current quality standard is reached between the manufacturer and the regulatory authorities prior to marketing pharmaceutical products. This agreement, which forms a key element of the "Marketing Authorization" is similar to a legal contract in which the company producing and controlling the product is committed to meeting quality criteria in future, i.e., prospectively, which are based on experience gained in the past while developing the product, i.e., retrospectively.

Quality standards are published by national regulatory authorities. Since the adoption of the first European Directive on pharmaceuticals (65/65/EEC) in 1965, the Member States of the European Union (EU) have been working towards harmonization of their requirements. These requirements have been published in "The Rules Governing Medicinal Products in the European Union" Volume 3" Medicinal Products for Human Use: Guidelines, Vol 3A "Quality and biotechnology" (http://ec.europa.eu/enterprise/-pharmaceuticals/eudralex/homev3.htm)

In the US, the quality standards are available through FDA's (FDA = Food and Drug Administration) homepage (http://-www.fda.gov/cder/guidance/index.htm) or via the Code of Federal Regulations (CFR) Title 21 (http://www.access.gpo.gov/cgi-bin/-cfrassemble.cgi?title=200621)

Some manufacturers achieve their goal of ensuring consistent quality by implementing Process Analytical Technology (PAT), a system for designing, analyzing, and controlling manufacturing through measurements of critical attributes of raw and in-process materials and processes during the manufacturing process (ICH Guideline Pharmaceutical Development – Q8 – http://www.ich.org/-LOB/media/MEDIA1707.pdf).

Product quality should be maintained throughout the product lifecycle, i.e., all phases in the life of a product from the initial development through marketing until the product's discontinuation. Attributes that are important to the quality of the pharmaceutical product should remain consistent with those used in the clinical trials. An effective quality risk management approach can ensure the high quality of the pharmaceutical product by identifying and controlling potential quality issues during development and manufacturing. Information from pharmaceutical development studies can be a basis for quality risk management. Quality risk management is a systematic process for the assessment,

control, communication and review of risks to the quality of the pharmaceutical product across the product lifecycle. (ICH Guideline Quality Risk Management – Q9 – http://www.ich.org/-LOB/media/MEDIA1957.pdf).

4.3.1. Manufacturing of Substances – Test of Starting Materials

All starting materials have to be tested according to adequate quality standards applying suitable analytical procedures before manufacturing or synthesizing an active substance. A chain of documents is generated as chemical synthesis proceeds. This documentation includes, amongst others, a written description of the process and appropriate production records, records of the raw materials used, records of batch numbers, records of the critical processing steps accomplished, and intermediate test results.

4.3.2. Control of Active Substances: Impurities

Impurities in active substances can be classified as organic impurities, inorganic impurities, and residual solvents. Process- and substance-related *organic impurities* may arise during the manufacturing process and/or storage of the active substance. They may be identified or unidentified, volatile or non-volatile, and include starting materials, byproducts, intermediates, degradation products, reagents, ligands, and catalysts. *Inorganic impurities* are normally known and identified and include reagents, ligands and catalysts, heavy metals, inorganic salts, and other materials, such as, filter aids and charcoal. *Residual solvents* are inorganic or organic liquids used as vehicles for the preparation of solutions or suspensions in the synthesis of an active substance.

The amount of impurities, identified or unidentified, must be limited to ensure the safety of patients. The procedure used to establish acceptable thresholds is described in detail in the ICH *Guideline "Impurities in New Drug Substances (Q3A)"*, (http://www.ich.org/LOB/-media/MEDIA422.pdf).

The levels of residual solvents in medicinal products should be no higher than can be supported by the safety data. Solvents that are known to cause unacceptable toxicity, such as, benzene, should be avoided in the production of active substances, excipients, or medicinal products unless their use can be strongly justified in a risk-benefit assessment. Solvents associated with less severe toxicity, e.g., chloroform, methanol, or toluene, should be limited in order to protect patients from potential adverse effects. Ideally, less toxic solvents, such as acetone, ethanol, or ethyl ether, should be used where viable.

A method for classifying residual solvents by risk assessment is provided in the *ICH Guideline "Impurities: Guideline for Residual Solvents (Q3C)"* (http://www.ich.org/LOB/media/-MEDIA423.pdf).

4.3.3. Control of Pharmaceutical Products: Impurities

Impurities in pharmaceutical products may be produced by degradation of the active ingredient or by reaction of the active ingredient with an excipient and/or with the immediate container/closure system. Consequently, the amount of degradation products allowed in a pharmaceutical product should be such that the therapeutic efficacy of the product is not affected. The toxicity of degradation products must also be evaluated and assessed.

Levels of degradation products can be measured, for example, by comparison of an analytical response for a degradation product to that of an appropriate reference standard or to the response of the active ingredient itself. Methods for setting up limits for degradation products are described in detail in the *ICH Guideline " Impurities in New Drug Products (Q3B)"* (http://-www.ich.org/LOB/media/MEDIA421.pdf).

4.3.4. Specifications

A specification is defined as a list of tests, references to analytical procedures, and appropriate acceptance criteria, which are numerical limits, ranges, or other criteria for the tests described. It establishes the set of criteria to which a drug substance or drug product should conform to be considered acceptable for its intended use. "Conformance to specifications" means that the

active substance and/or pharmaceutical product, when tested according to the listed analytical procedures, will meet the listed acceptance criteria. Specifications are critical quality standards that are proposed and justified by the manufacturer and approved by regulatory authorities as conditions of approval.

ICH Guideline "Specifications: Test Procedures and Acceptance Criteria for New Drug Substances and New Drug Products: Chemical Substances – Q6A (http://www.ich.org/LOB/-media/MEDIA430.pdf). Decision trees: http://-www.ich.org/LOB/media/MEDIA431.pdf

ICH Guideline "Specifications: Test Procedures and Acceptance Criteria for Biotechnological/Biological Products – Q6B (http://-www.ich.org/LOB/media/MEDIA432.pdf).

4.3.5. Validation of Analytical Procedures

The objective of analytical procedure validation is to demonstrate that the method in question is suitable for its intended purpose. The following analytical procedures have to be validated in particular:

- Identification tests intended to ensure the identity of an analyte in a sample by comparing a property of the sample to that of a reference standard
- Quantitative tests for the content of impurities
- Limit tests for the control of impurities
- Quantitative tests of the active moiety in the active substance or pharmaceutical product
- Dissolution testing for pharmaceutical products
- Particle size determination for active substances

The following characteristics should be considered during the validation of analytical procedures:

Accuracy	closeness of agreement between value accepted and value found;
Precision	closeness of agreement between a series of measurements obtained from multiple sampling of the same homogeneous sample;
Repeatability	precision under same operating conditions over a short interval of time;
Intermediate Precision	within-laboratories variations: different days, different analysts, different equipment;
Reproducibility	precision between different laboratories;
Specificity	ability to assess unequivocally the analyte in the presence of components, which may be expected to be present;
Detection limit	lowest amount of analyte in a sample which can be detected;
Quantitation limit	lowest amount of analyte in a sample which can be quantitatively determined;
Linearity	results directly proportional to the concentration of analyte in the sample;
Range	interval between the upper and the lower concentration of analyte in the sample for which it has been demonstrated that the analytical procedure has a suitable level of precision, accuracy and linearity;
Robustness	capacity to remain unaffected by small variations in method parameters.

Relevant information on validation of analytical procedures is provided in the *ICH Guideline "Validation of Analytical Procedures: Text and Methodology – Q2(R1)"* (http://-www.ich.org/LOB/media/MEDIA417.pdf).

4.3.6. Process Validation and Qualification

Since it is important to ensure that the defined quality standards of the pharmaceutical product are met, the manufacturers conduct "Process Validation and Qualification" on the product prior to marketing thereby establishing and documenting that:

- The facilities, equipment and processes have been designed in compliance with the requirements of the current GMP guidelines.
- The facilities and equipment have been built and installed as specified. This constitutes the Installation Qualification (IQ).
- The facilities and equipment are operated as specified. This constitutes the Operational Qualification (OQ).
- The facilities and equipment operate as specified and repeatedly and reliably produce a finished product of the requisite quality. This constitutes the Process Validation (PV).

Any aspect of the premises, facilities, equipment or processes, which may affect the quality of the product, either directly or indirectly, is subject to qualification and validation (*Convention for the Mutual Recognition of Inspections: "Principles of Qualification and Validation in Pharmaceutical Manufacture," Document PH 1/96*, January 1996).

Continuous Process Verification is an alternative approach to process validation in which manufacturing process performance is continuously monitored and evaluated.

4.3.7. Batch Release

If an active substance or a pharmaceutical product meets all quality criteria as previously agreed with the regulatory authorities, the Qualified Person (QP) or the member of the Quality Assurance organization in charge within the organization of the manufacturer can release the batch for further processing or marketing.

Some types of pharmaceutical products, e.g., vaccines, sera, toxins, antitoxins, antigens, blood products, etc., have to be tested and released on a batch-by-batch basis by an independent state laboratory specializing in this particular analytical area. These products contain substances whose purity and potency cannot be measured by chemical methods alone.

4.3.8. Stability Testing

Stability studies are a major expense when developing new products. This applies in particular to pharmaceutical products that are to be marketed in several strengths and package types. Multiple strengths and package types combined with multiple batches, various storage conditions, test parameters, and test intervals require a great number of samples to be tested at considerable cost. Further to this, the different requirements of the regulatory agencies must be taken into account. As a result, an enormous amount of stability testing, much of it redundant, was performed by multinational pharmaceutical companies seeking approvals in several countries. Therefore, the compilation of a common set of stability requirements for marketing authorizations was considered to be a top priority for the pharmaceutical industry when the International Conference on Harmonisation of Technical Requirements for the Registration of Pharmaceuticals for Human Use (ICH) was formed in 1991. Regulators and pharmaceutical industry representatives from the EU, Japan, and the United States with observers from the Canadian and Swiss Health Authorities and the WHO chose stability testing as one of the first issues to be discussed and harmonized. An ICH Guideline on Stability Testing was subsequently developed and published in 1993, after which it was adopted throughout the ICH region [4]. This guideline describes the stability testing requirements for a registration application within the "ICH territory": EU, Japan, and the USA *(ICH Harmonized Tripartite Guideline "Stability Testing of New Drug Substances and Products – Q1A")* of 27 October 1993, as amended in 2003 (http://www.ich.org/-LOB/media/MEDIA419.pdf)

Meanwhile, additional ICH stability guidelines have been developed:

- *Photostability Testing of New Drug Substances and Products (Q1B)* http://-www.ich.org/LOB/media/MEDIA412.pdf
- *Stability Testing for New Dosage Forms (Q1C)* http://www.ich.org/LOB/media/-MEDIA413.pdf
- *Bracketing and Matrixing Designs for Stability Testing of New Drug Substances and Products (Q1D)* http://www.ich.org/LOB/media/-MEDIA414.pdf
- *Evaluation of Stability Data (Q1E)* http://-www.ich.org/LOB/media/MEDIA415.pdf
- *Stability Testing of Biotechnological/Biological Products (Q5C)* http://www.ich.org/-LOB/media/MEDIA427.pdf

In Europe, additional note for guidance has been published by regulators, which address specific aspects not covered by ICH:

- *Note for Guidance on Inclusion of Antioxidants and Antimicrobial Preservatives in Medicinal Products* (CPMP/CVMP/QWP/115/95) http://www.emea.eu.int/pdfs/human/qwp/-011595en.pdf
- *Note for Guidance on Start of Shelf –Life of the Finished Dosage Form* (CPMP/QWP/072/96) http://www.emea.eu.int/pdfs/human/qwp/-007296en.pdf
- *Note for guidance on Maximum Shelf-Life for Sterile Products after First Opening or following Reconstitution* (CPMP/QWP/159/96 corr) http://www.emea.eu.int/pdfs/human/-qwp/015996en.pdf
- *Guideline on Stability Testing for Applications for Variations to a Marketing Authorization* (CPMP/QWP/576/96/Rev 1) http://www.emea.eu.int/pdfs/human/qwp/-057696en.pdf
- *Note for guidance on Declaration of Storage Conditions A) in the Product Information of Medicinal Products, B) for Ac-*

Table 10. The CZs, Definition and criteria and long-term testing conditions

CZ	Definition	Criteria	
		Mean annual temperature measured in the open air/Mean annual partial water vapor pressure	**Long-term testing conditions**
I	Temperate climate	$\leq 15°C / \leq 11 \times 10^2$ Pa	21°C / 45% RH
II	Subtropical and Mediterranean climate	> 15 to $22°C / > 11$ to 18×10^2 Pa	25°C / 60% RH
III	Hot and dry climate	$> 22°C / \leq 15 \times 10^2$ Pa	30°C / 35% RH
IVA	Hot and humid climate	$> 22°C / > 15$ to 27×10^2 Pa	30°C / 65% RH
IVB	Hot and very humid climate	$> 22°C / > 27 \times 10^2$ Pa	30°C / 75% RH

tive Substances (CPMP/QWP/609/96/Rev 1) http://www.emea.eu.int/pdfs/human/qwp/-060996en.pdf

– *Note for guidance on In-Use Stability Testing of Human Medicinal Products* (CPMP/QWP/2934/99) http://www.emea.eu.int/pdfs/human/qwp/-293499en.pdf
– *Stability Testing of Existing Active Substances and Related Finished Products* (CPMP/QWP/122/02, rev 1) http://www.emea.eu.int/pdfs/human/qwp/-012202en.pdf

The US FDA has adopted meanwhile all ICH stability guidelines.

As the ICH guidelines are limited to new active substances and products for human use marketed in ICH countries in which climatic conditions are moderate, the World Health Organization (WHO) developed its own guideline to include established substances, and also hot or hot and humid climatic zones (CZs). The WHO guideline was published in 1996 (*"Guidelines for stability testing of pharmaceutical products containing well-established drug substances in conventional dosage forms" WHO Technical Report Series, No. 863*, 1996) [5]. According to this guideline, the recommended long term testing for hot and humid countries is 30°C/70% RH, a condition, which was changed in 2001 to 30°C/65% RH (*Report of the 37th meeting of the WHO Expert Committee on Specifications for Pharmaceutical Preparations, Geneva, 22-26 October 2001. WHO Technical Report Series 908, 2003, page 13).*

The 40th WHO Expert Committee on Specifications for Pharmaceutical Preparations met in Geneva in October 2005, and decided to split the current CZ IV (hot and humid countries) into CZ IVA – for which 30°C/65% RH will remain the standard long-term testing condition – and CZ IVB, for which, if justified, 30°C/75% RH will become the testing condition

Table 10 gives criteria [6] and long-term testing conditions assigned to the CZs of the world.

National regulatory authorities in countries outside the ICH region developed stability requirements, which are either adopting ICH guidelines, e.g., Switzerland, Norway, Iceland, Canada, Australia, or are based on the original ICH text but with additional or different testing conditions, e.g., Brazil, and ASEAN.

4.3.9. Documentation

Format of Registration Documentation. Regulatory authorities in various regions require applicants to submit marketing authorization applications according to their national guidelines and regulations. In *Europe*, the format for presenting quality related documents is outlined in detail in *The Rules governing Medicinal Products in the European Union, Volume 2B: Notice to Applicants*, June 2004, to be found at. http://pharmacos.eudra.org/F2/eudralex/vol-2/B/ctd_06-2004.pdf.

The format for applications in the *USA* is described in the *Code of Federal Regulations, Title 21, Chapter I, Subchapter D, Part 314.50* (http://a257.g.akamaitech.net/7/257/-2422/10apr20061500/edocket.access.gpo.gov/-cfr_2006/aprqtr/pdf/21cfr314.50.pdf).

In *Japan*, the Ministry of Health and Welfare regularly publishes updates of their Technical Requirements for New Drug Applications, updated versions are available from Yakuji Nippo, Ltd., Japan, editorial supervision by the Pharmaceuticals and Cosmetics Division, Pharmaceutical Affairs Bureau, Japanese Ministry of Health and Welfare.

The Common Technical Document – Quality The ICH Expert Working Group "Common Technical Document (CTD) Quality" developed a common structure (ICH M4 Q – http://-www.ich.org/cache/compo/276-254-1.html) for the chemical/pharmaceutical section of dossiers for marketing authorization applications. The final ICH guideline, which has been released in 2000, is regarded as a major achievement, and the result of a concerted effort on the part of the regulatory reviewers and pharmaceutical industry (see also Section The Common Technical Document).

Many regulatory authorities worldwide have adopted the ICH CTD as the standard format for submitting applications for clinical trials, new marketing authorizations, and variations.

In the following, the structure of the CTD Quality module is listed.

Drug Master Files. Drug Master Files (DMFs) are documents that are submitted to the U.S. FDA providing confidential detailed information on the facilities, processes, or articles used in the manufacturing, processing, packaging, and storage of medicinal products intended for human use. DMFs allow parties other than the holder of the DMF to reference information not disclosed to them (Center for Drug Evaluation and Research, FDA *Guideline for Drug Master Files*, September 1989, to be found at http://www.fda.gov/cder/guidance/dmf.htm).

In the EU, the use of Drug Master Files is restricted to active substances only (*CHMP Guideline on Active Substance Master File Procedure, London, 15 April 2005 – Rev 2 published on 24 May 2006* (http://www.emea.eu.int/pdfs/-human/qwp/022702en.pdf)

Drug Substance	
General information	
Nomenclature	Recommended INN[a], compendial name, if relevant, chemical name(s), company or laboratory code, national name, e.g., BAN[b], USAN[c], JAN[d], and CAS registry number.
Structure	NCE: structural formula, including relative and absolute stereochemistry, the molecular formula, and relative molecular mass. Biotech: schematic amino acid sequence indicating glycosylation sites and relative molecular mass.
General properties	Physicochemical and other relevant properties.
Manufacture	
Manufacturer(s)	Name, address, and responsibility of each manufacturer and each proposed production site or facility.
Description of manufacturing process and process controls	Description of the manufacturing process and process controls: flow diagram, quantities of raw materials, solvents catalysts and reagents, identification of critical steps, operating conditions such as temperature, pressure, pH, and time. Additionally for Biotechnology: Batch and scale definition; flow diagram from original inoculum up to the last harvesting operation; description of each process step including purification and modification reactions; filling procedure; container closure system; storage and shipping conditions.
Control of materials	List of raw materials, starting materials, solvents, reagents, catalysts; information on their quality and control. Additionally for biotech products: viral safety information, source of the cell substrate and analysis of the expression construct; cell banking system, quality control activities, cell-line stability.
Control of critical steps and intermediates	Critical steps: Tests and acceptance criteria performed at critical steps of the manufacturing process. Intermediates: Quality and control of intermediates.
Process validation and/or evaluation	Studies for aseptic processing and sterilization.
Manufacturing process development	Description of the significant changes made to the manufacturing of the drug substance used in producing non-clinical, clinical, scale-up, pilot, and production scale batches.
Characterization	
Elucidation of structure and other characteristics	NCE: Confirmation of structure based on synthetic route and spectral analyses, for example. Information on the potential for isomerism, the identification of stereochemistry, or the potential for forming polymorphs. Biotech: details on primary, secondary, and higher-order structure post-translational forms, biological activity, purity, and immunochemical properties.
Impurities	
Control of Drug Substance	
Specification	
Analytical Procedures	
Validation	
Batch Analyses	
Justification	

Reference standards or materials	Information on the reference standards or reference materials used for testing of the drug substance.
Container closure system	Description of the container closure system identity of materials of construction and their specifications; suitability with respect to choice of materials, protection from moisture and light, compatibility of the materials of construction with the active substance.
Stability	
Stability summary and conclusions	Types of studies conducted, protocols used, and the results obtained; conclusions with respect to storage conditions and retest date or shelf-life.
Stability data	Results of the stability studies in an appropriate format such as tabular, graphical, narrative; information on analytical procedures used and their validation.

[a] INN = Recommended International Non-Proprietary Names.
[b] BAN = British Approved Names.
[c] USAN = United States Adopted Names.
[d] JAN = Japanese Accepted Names.

Drug product

Description and composition	Description of the dosage form, list of all components, and their amount, their function, reference to their quality standards, type of container and closure used.
Pharmaceutical Development	Information on the development studies conducted to establish that the dosage form, the formulation, manufacturing process, container closure system, microbiological attributes and usage instructions are appropriate for the purpose specified.
Components of the drug product	Compatibility of the active substance with excipients; key physicochemical characteristics of the active substance; choice of excipients.
Drug product	Summary describing the development of the drug product; justification of overages; physicochemical parameters; and biological properties.
Manufacturing process development	Selection and optimization of the manufacturing process.
Container closure system	Suitability of the container closure system, choice of materials, protection from moisture and light, compatibility of the materials of construction with the dosage form.
Microbiological attributes	Microbiological attributes of the dosage form; selection and effectiveness of preservative systems.
Compatibility	Compatibility of the drug product with reconstitution diluent(s) or dosage devices.
Manufacture	
Manufacturer(s)	Name, address, and responsibility of each manufacturer, and each site or facility involved.
Batch formula	List of all components, their amounts, and a reference to their quality standards.
Description of manufacturing process and process controls	Flow diagram, description of the process, and type of equipment; process parameters.
Controls of critical steps and intermediates	Critical steps: tests and acceptance criteria, with justification, including experimental data, performed at critical steps. Intermediates: information on the quality and control of intermediates isolated during the process.
Process validation and/or evaluation	Description, documentation, and results for critical steps or critical assays used in the manufacturing process.
Control of excipients	
Specifications	
Analytical procedures	
Validation	
Justification	
Excipients of human or animal origin	
Novel excipients	For excipients used for the first time, full details of manufacture, characterization, and controls.
Control of drug product	
Specification(s)	
Analytical procedures	
Validation	
Batch analyses	
Characterization of impurities	
Justification	
Reference standards or materials	Information on the reference standards or reference materials used for testing of the product
Container closure system	Description of the container closure systems , including identity and specification of each component.
Stability	
Stability summary and conclusion	Types of studies conducted, protocols used, and the results. Conclusions with respect to storage conditions and shelf-life, and, if applicable, in-use storage conditions and shelf-life.
Stability data	Results of the stability studies conducted in an appropriate format such as tabular, graphical, narrative; information on analytical procedures used and their validation.

4.3.10. Variations – Changes

Manufacturers are required to amend and update manufacturing and control methods to take account of scientific and technical progress within the lifetime of a medicinal product. In Europe, this is detailed in Article 23 of Directive 2001/83/EC/EC and Article 16(2) of Regulation 726/2004. Since the level of scientific development is constantly subject to change, modifications in a product's composition, manufacturing and control methods are unavoidable, and even desirable as they may improve quality. However, every change that is made entails revision and amendments to the documentation. Sometimes approval has to be obtained from the health authorities before the proposed changes can be implemented (http://ec.europa.eu/-enterprise/pharmaceuticals/eudralex/vol-2/a/-v2a_chap5_r1_2004-02.pdf).

In the USA, regulation 21 CFR 314.70 (http://a257.g.akamaitech.net/7/257/2422/-10apr20061500/edocket.access.gpo.gov/-cfr_2006/aprqtr/pdf/21cfr314.70.pdf) provides regulatory requirements for changes subject to FDA approval prior to implementation, and for changes that can be reported to the FDA in an annual report.

4.3.11. Change Control

To ensure that the systems concerned are continuously validated, the manufacturer must monitor all changes with respect to facilities, materials, equipment, and processes used in the manufacture of active substances and pharmaceutical products. This commitment should be declared in the Validation Master Plan. As part of its Quality Management System, the manufacturer must establish a defined, formalized change control procedure.

4.3.12. Compliance

Manufacturers must make sure that the CMC documentation approved by the regulatory authorities complies with the methods applied in the manufacturing and quality control of the active substances and products.

4.3.13. Changes Requiring New Applications – Line Extension

Certain changes to a marketing authorization are considered to fundamentally change the terms of the authorization in question and therefore cannot be considered as a variation. For example:

- Changes to the active substance(s)
- Changes to strength (= the quantitative composition in terms of active substance)
- Changes to pharmaceutical form/dosage form
- Changes to route of administration

http://ec.europa.eu/enterprise/pharmaceuticals/-eudralex/vol-2/c/v2c_ea_v__10_2003.pdf

An abridged application for a new marketing authorization must be submitted for these changes and, in certain cases, the existing marketing authorization may have to be withdrawn. Otherwise, the new product is regarded as a "line extension" to the existing formulations and dosage forms.

4.3.14. Inspections

Regulatory authorities regard the marketing authorization as a contract between the manufacturers and themselves, based on the CMC information submitted and the satisfactory GMP status of the manufacturing site. In order to verify that data, processes and control methods submitted are accurate and complete, external inspectors are visiting the facilities and functions on a regular basis. Differences observed between submitted data and reality are cause for concern as the pharmaceutical product on the market may be "out of compliance". The inspectors must establish whether the control methods are applied and the facilities adequate, the personnel properly trained and manufacturing procedures followed. The inspectors also have to check whether cross-contamination can be excluded, i.e. whether the substance or product is subject to contamination by material stored or used in the same building. Other factors to be considered are:

- The degree of exposure of the material to adverse environmental conditions;
- Relative ease and thoroughness of clean-up;

– The risk of microbial contamination during aseptic processing of a sterile product.

The inspections may take place during the clinical development of a new substance, prior to granting marketing authorization (pre-approval inspection), or during the marketing phase.

4.3.15. The Mutual Recognition Agreement (MRA)

To cut down on the need for GMP inspections by regulatory authorities in foreign countries, agreements came into operations between the European Community and Canada, Australia, New Zealand, Switzerland and Japan (http://-ec.europa.eu/enterprise/pharmaceuticals/mra/-doc/statusreport20041018.pdf). It has been agreed to exchange certificates of GMP compliance for manufacturers, and batch certificates.

The main advantage of an MRA is the assurance that imported pharmaceutical products meet GMP requirements without resource expenditures on the part of the authorities of the importing country. Another important benefit of an MRA is a reduction of costs for the pharmaceutical manufacturer, mainly as a result of inspection reports being accepted by more than one regulatory authority. This eliminates the need for duplication of inspections and imply fewer inspections of the manufacturing sites. An MRA also reduces regulatory review times as it increases the efficiency of pre-marketing approval inspection activities.

4.3.16. Pharmaceutical Inspection Convention (PIC)

Another initiative to cut down on foreign GMP inspections is the "Convention for the Mutual Recognition of Inspections in respect of the Manufacture of Pharmaceutical Products" (shortened to Pharmaceutical Inspection Convention or PIC). This convention was signed in October 1970 by all EFTA countries at the time (i.e., Austria, Denmark, Finland, Iceland, Liechtenstein, Norway, Portugal, Sweden, Switzerland, and the United Kingdom). Since coming into force the convention has been extended to include Hungary, Ireland, Romania, Germany, Italy, Belgium, France, and Australia.

Similar to the MRAs mentioned above, the "PIC provides that an inspection of a pharmaceutical manufacturer, whose intention it is to export products in one of the Contracting States, is carried out by its national authority and shall be regarded and assessed by the health authority of the country of importation as if it had been carried out by its own inspectors."

A Committee of Officials supervises the operation of the PIC concerning the technical aspects of the manufacturing and control of pharmaceuticals. In the meantime, the convention's original scope has been extended to the training of laboratory staff, the mutual recognition of the quality standards of inspectorates, and also to cooperation concerning blood products, radiopharmaceuticals, medicinal gases, etc. Working groups meet regularly to develop guides, guidelines, and recommendations. Also seminars on technical subjects are organized, and the proceedings of these seminars and experts' meetings are published

4.3.17. Pharmaceutical Inspection Cooperation Scheme (PIC/S)

Some of the contracting states within the PIC are also Member States of the European Union with the result that certain rules and regulations were incompatible. Therefore, a new arrangement, which may eventually replace the PIC, called "Pharmaceutical Inspection Cooperation Scheme" (or PIC Scheme) has been set up and commenced operating in 1995. This new scheme is meant to be less formal and more flexible concerning cooperation between the inspectorates of the present PIC contracting states. Also the PIC Scheme allows for inspectorates of other countries to join. In addition to the recognition of foreign inspections, the PIC Scheme is in harmony with the main tasks of the PIC, namely, "the exchange of information, networking and confidence building between the national inspection authorities, the development of quality standards systems, the training of inspectors and other related experts and its work towards the global harmonization of Good Manufacturing Practice (GMP)".

The contracting members of the PIC Scheme are the following inspectorates: Australia, Austria, Belgium, Canada , the Czech Republic,

Denmark, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Latvia, Liechtenstein, Malaysia, the Netherlands, Norway, Poland, Portugal, Romania, Singapore, the Slovak Republic, Spain, Sweden, Switzerland, and the United Kingdom. Observers are Estonia, the EMEA, UNICEF, and WHO. In addition, the following applications for membership are being considered: Estonia, South Africa, and Taiwan.

http://www.picscheme.org/indexnoflash.php

4.3.18. Pharmacopoeias

National Pharmacopoeias: In order to establish and maintain a scientific/technical standard for the quality of medicines, lists of active substances, excipients, and pharmaceutical products, their preparation, control, and use were developed and published in a "pharmacopoeia". The earliest of these was probably the "New Compound Dispensatory" issued in 1498 by the "Florentine Guild of Physicians and Pharmacists". Various pharmacopoeias were generated in the ensuing centuries: Barcelona (1535), Nürnberg (1546), Cologne (1565), Rome (1583), and London (1618). The first attempt to harmonize different standards and monographs was made by the Pharmacopoeia Committees of London, Edinburgh and Dublin. As the result of their efforts, the first "British Pharmacopoeia" documenting the agreement on harmonized international quality standards was published in 1864 [7].

International Pharmacopoeia: The project of developing an "International Pharmacopoeia" started in 1929 with an agreement signed by 19 countries. The next step was not made until 1948, when the first World Health Assembly established an expert committee to adapt and harmonize the existing monographs of major pharmacopoeias, and also to develop new standards. As the committee also kept developing countries in mind, some of the active substances included in the first edition of the International Pharmacopoeia were for the treatment of tropical diseases. Analytical methods are adapted for the practice of quality control testing in countries that need inexpensive methods, such as on-the spot identification of counterfeit pharmaceuticals (WHO Drug Information Vol. 13, No. 1, 1999, pp. 13 – 14).

European Pharmacopoeia: The need to unify the various national pharmacopoeias in Europe arose as a result of the proposal to allow the free movement of medicinal products within the European Community. Both public health and international trade require common manufacturing and quality control standards concerning active substances for human and veterinary use. It also requires these standards be updated to stay in line with scientific progress. In 1964, the "European Pharmacopoeia Convention" was signed by eight Member States of the Council of Europe. It is open to European countries (members and, under certain conditions, non-members of the Council of Europe), as well as to an international European organization. Observer status is also possible.

Thirty-five parties (in 2006) are members of the Convention including 24 EU member states): Austria, Belgium, Bosnia and Herzegovina, Bulgaria, Croatia, Cyprus, Czech Republic, Denmark, Estonia, Finland, Macedonia, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, the Netherlands, Norway, Portugal, Romania, Serbia and Montenegro, the Slovak Republic, Slovenia, Spain, Sweden, Switzerland, Turkey, the United Kingdom; and the Commission of the European Union.

A further 18 parties participate as observers: Albania, Georgia, Poland, and the Ukraine, as well as the non-European countries Algeria, Australia, Brazil, Canada, China, Israel, Madagascar, Malaysia, Morocco, Senegal, Syria, Tunisia, United States of America, and the WHO. Some of these observers have implemented all or parts of the European Pharmacopoeia in their national pharmaceutical regulations (http://www.pheur.org/-site/page_608.php).

The European Pharmacopoeia (EP or Ph. Eur.) features more than 280 general analytical methods on which the specifications prescribed in the monographs are based. The methods range from physical, chemical and biological to microbiological, phytochemical, and so on. The EP also includes technical methods used to test the functional parameters of pharmaceutical forms such as the dissolution test for tablets.

The texts are updated at regular intervals to take into account scientific progress and any changes in the commercial products. The prin-

ciples of monograph compilation are adapted to accommodate regulatory requirements in the public health area (licensing, control and inspection authorities), industrial constraints and recent advances in technology and science (http://www.pheur.org/).

The monographs and methods published in the European Pharmacopoeia are normally transferred to the national pharmacopoeias, e.g., the *Deutsches Arzneibuch* (DAB), the British Pharmacopoeia (BP), the Pharmacopeé Francaise, the Farmacopeia Ufficiale della Republica Italiana.

In marketing authorization application dossiers submitted to regulatory authorities in the EU Member States, the monographs of the European Pharmacopoeia are obligatory.

The European Pharmacopoeia Commission has set the goals of rapidly adding to the number of existing European monographs (2000 so far), reducing the time taken to compile them, and, if necessary, generating monographs on recent substances still protected by patent.

Cooperation between the Council of Europe and the EU was further advanced on 26 May 1994, when the "European Pharmacopoeia Secretariat" took over additional objectives, e.g., setting up a European network of laboratories involved in the quality control of pharmaceutical products. Consequently, the "European Pharmacopoeia Secretariat" changed its name to the "European Department for the Quality of Medicines" (EDQM). This European network, called the Official Medicines Control Laboratories (OMCLs), is open not only to EU countries but also to members and observers of the European Pharmacopoeia Commission. Its main objectives are to achieve the mutual recognition of tests carried out at the national level for countries that belong to the EU, and the sharing of expertise, standardization and international collaboration for the other countries.

The European Pharmacopoeia is one of the co-founders of the Pharmacopoeia Discussion Group (PDG) that was set up in 1990 with the Japanese Pharmacopoeia (JP) and the United States Pharmacopeia (USP). Monographs and general methods of analysis proposed by national associations of manufacturers of pharmaceutical products are selected for harmonization in the three pharmacopoeias.

Unites States Pharmacopeia: In contrast to other pharmacopoeias, the Unites States Pharmacopeia (USP) is a corporation, not a governmental institution. Founded in 1820, it became the official public standards-setting authority for all prescription and over-the-counter medicines, dietary supplements, and other healthcare products manufactured and sold in the United States. The USP is funded through revenues from the sale of products, e.g. reference standards, and services (http://www.usp.org/aboutUSP/).

4.3.19. The EP Certificate of Suitability

Global expansion of international trade has given rise to a wide range of qualities of active substances within the territory covered by the Convention on the Elaboration of a European Pharmacopoeia. The great variety of supply sources has made it necessary to take additional measures to protect public health so that the European Pharmacopoeia can continue to play its role as a reliable reference in defining the quality of medicines. It is essential to have a procedure that allows the manufacturer of active substances to prove that the purity of the substance is suitably controlled by the EP monograph (http://www.pheur.org/site/page_625.php).

The Procedure is based on a Resolution of the Public Health Committee (Partial Agreement, Resolution AP-CSP (99) 4) (APCSP9904E). Under this official procedure, manufacturers or suppliers of substances for pharmaceutical use can apply for a certificate concerning

- the evaluation of the suitability of the monograph for the control of the chemical purity and microbiological quality of their substance according to the corresponding specific monograph, or
- the evaluation of reduction of Transmissible Spongiform Encephalopathy (TSE) risk, according to the new general monograph, or both.

This procedure is aimed at facilitating and simplifying exchanges between the partners to ensure that the quality of substances is guaranteed and that these substances comply with the European Pharmacopoeia.

1. Introduction

Phase-transfer catalysis (PTC) is a synthetic organic method and manufacturing process technology that is applied successfully in a wide range of organic reactions. Products manufactured in 1989 by processes that include at least one major PTC step are estimated to represent approximately $\$ 10\times10^9$ per year in sales. The major areas of application are the production and modification of polymers and monomers ($\$ 5\times10^9$), pharmaceuticals ($\$ 3\times10^9$), and agrochemicals ($\$ 2\times10^9$). Lesser commercial applications include the preparation of dyes, flavors, and fragrances.

Table 1. Applications of phase-transfer catalysis

PTC/X^- *	PTC/OH^-
Halide exchange	Alkylation (C-, O-, N-, S-)
Esterification	Asymmetric induction
Other nucleophilic substitutions (CN^-, RS^-, N_3^-, SCN^-, etc.)	Dehydrohalogenation
Oxidation	Condensation (Wittig, aldol, Darzens)
Reduction	Michael addition
Benzoin condensation	Hydrolysis
Polymerization	Deuterium exchange
	Isomerization
	Carbene addition
	Organometallic applications

* X^- = Anion other than OH^-.

Most PTC reactions involve the transfer of an anionic species from an aqueous or solid phase or interface to an organic phase. The transferred species then reacts with enhanced reactivity due to decreased hydration, increased concentration, or enhanced proximity of the reactants. In successful applications the result is high yield under mild reaction conditions. Because numerous organic reactions involve anions, either as reactants or catalysts (see Fig. 1), PTC is a highly attractive process option for a wide scope of reactions (see Table 1). Many of the attributes of PTC systems are advantageous from the standpoint of process engineers and chemists.

2. Mechanism and Optimization Ramifications

The mechanism of PTC reactions is illustrated in Figure 2. According to the extraction mechanism [1], a typical catalyst, such as a quaternary ammonium cation (symbolized by Q^+), forms an ion pair with an anionic reactant X^-, which equilibrates between an organic and an aqueous or solid phase. Once in the organic phase, the anion reacts with enhanced reactivity (due to reduced hydration) with a typical substrate RY to yield the product RX and an anionic leaving group Y^- that pairs with the catalyst. In the aqueous or solid phase the catalyst exchanges the leaving group for another anionic reactant to complete the catalytic cycle.

Two extremes of representative behavior may be observed in these systems: (1) chemical reaction control and (2) mass-transfer control (intermediate combinations of these two extremes are possible and do occur). In most classical PTC reactions the rate-determining step is the chemical reaction (e.g., Q^+X^-+RY in the example in Fig. 2). *Chemical reaction controlled* reactions are characterized by increasing reactivity as the lipophilicity of the catalyst increases, the hydration of the anionic reactant decreases, and the polarity of the organic solvent decreases

Bases:	OH^-, HCO_3^-
Oxidizing agents:	MnO_4^-, $Cr_2O_7^{2-}$, ClO^-, O_2^-, IO_4^-, ClO_4^-, $[Fe(CN)_6]^{3-}$
Reducing agents:	BH_4^-, BH_3CN^-, $HCOO^-$, $[Fe(CO)_{12}]^{2-}$, $[Co(CN)_5H]^{3-}$, $[Co(CO)_4]^-$, $S_2O_4^{2-}$
Miscellaneous:	HCl, HBr, HI, H_2O_2, $RhCl_4^-$, CCl_3^-
Nucleophiles:	F^-, Cl^-, Br^-, I^-, CN^-, RO^-, ArO^-, $RCOO^-$, RS^-, N_3^-, SCN^-, OCN^-, NO_2^-, NO_3^-

Figure 1. Anions successfully transferred and/or reacted under phase-transfer catalysis conditions

[2]. They also show a tendency toward catalyst poisoning by "soft" anions (definition of "hard" and "soft" acids and bases according to PEARSON) [3]. Some PTC reactions are *mass-transfer controlled*, for example, when the rate-determining step is the transfer of the reacting anion into the bulk organic phase. Mass-transfer controlled reactions occur often when the anion to be transferred has a high charge density and the subsequent reaction is rapid. For example, many alkylations of activated methylene or N−H groups, preceded by hydroxide ion extraction, are limited in rate by the transfer of the hydroxide ion into the organic phase. These reactions were previously thought to proceed via a different mechanism [4] and were termed "interfacial mechanism reactions." Mass-transfer limited reactions involving the transfer of anions with high charge densities are characterized by (1) increasing reactivity as the "accessibility" of the positive charge on the quaternary nitrogen of the catalyst increases (until the catalyst is too hydrophilic to function); (2) a strong dependence on agitation efficiency [5]; and (3) increasing reactivity if polar solvents are used (such as methyl isobutyl ketone).

Figure 2. Extraction mechanism of phase-transfer catalysis

Empirically, PTC base-catalyzed reactions are often found to be mass-transfer limited for organic substrates that are not water soluble and have $pK_a < 23$. Not all PTC reactions involving transfer of hydroxide ions are mass-transfer limited [6], and mass-transfer control can also be observed with anions other than hydroxide (e.g., fluoride).

3. Catalysts

Most commercially available catalysts are quaternary ammonium and phosphonium salts, crown ethers, and open-chain polyethers (see Fig. 3).

Quaternary Ammonium Salts. Among the most useful quaternary salts ("quats") is tetrabutylammonium bromide [*1643-19-2*] (TBAB). Tetrabutylammonium bromide costs approximately $ 8.80/kg in tank car quantities and is recyclable by extraction [7]; its use has been reported in 450 patents describing both chemical reaction controlled and mass-transfer limited reactions. Other commercial quats include benzyltrimethylammonium chloride [*56-93-9*], methyltricaprylammonium chloride [*13275-89-3*] (Arosurf PT 64, trademark of Sherex; Aliquat 336 PTC, trademark of Henkel), and methyltributylammonium chloride [*56375-79-2*] (MTBC). The major ingredient of Aliquat 336 and Arosurf PT 64 is methyltrioctylammonium chloride. Both quats

Figure 3. Representative phase-transfer catalysts

are effective in both chemical reaction controlled and mass-transfer limited reactions. One drawback of this catalyst is that the product must usually be distilled to separate the catalyst, or the catalyst may be separated by adsorption on a laboratory scale. Methyltributylammonium chloride and triethylbenzylammonium chloride are excellent mass-transfer limited catalysts for phase transfer of hydroxide ions. Methyltributylammonium chloride costs approximately \$ 4.80/kg, has a low molecular mass, is recyclable by extraction, and has an LD_{50} of 933 mg/kg (rat, oral [8]).

Quaternary Phosphonium Salts. Phosphonium salts based on tributylphosphine can be considered for cases in which the use of quaternary ammonium salts may be limited because of elevated reaction temperature (120 – 150 °C) (decomposition); it cannot be used with hydroxide ions.

Crown Ethers and Open-Chain Polyethers. Among the *crown ethers* (→ Crown Ethers) 18-crown-6 and dicyclohexano-18-crown-6 effectively solubilize salts in organic media via coordination of inorganic cations by the many lone electron pairs on the oxygen atoms [9]. The cost of crown ethers for industrial use is high, although some specialty applications are likely that employ crude crown ethers (ca. \$ 100/kg) in small but effective quantities. In addition, crown ethers are thought to be toxic. Openchain polyethers such as poly(ethylene glycols) (PEGs) and tris(dioxa-3,6-heptyl)amine [*70384-51-9*] (TDA-1) (Rhône-Poulenc) [10] are phase-transfer catalysts that act by coordination similar to crown ethers. The biological properties of these open-chain polyethers are more suitable for industrial use; the LD_{50} of PEG-400 (i.e., PEG with M_r=400) is 33 g/kg [11]; of TDA-1, 4 g/kg [12]. The PEGs are competitive in price with quaternary salts (ca. \$ 1.30/kg), whereas TDA-1 is more expensive (ca. \$ 42.10/kg in 1 200-kg lots).

The PEGs are sometimes as active as crown ethers, but larger quantities of PEGs are usually needed [13].

Newer Developments. *Chiral catalysts* and *high-temperature catalysts* are examples of novel catalysts with great potential commercial application. Merck, Sharp & Dohme has successfully employed chiral quaternized cinchona alkaloids to attain desired enantiomers with high enantiomeric excess and yield (both > 94 %) [14]. Significant understanding of this system has been achieved [15]. General Electric has shown the utility of *N*-(2-ethylhexyl)-4-(*N′*,*N′*-dimethylamino)pyridinium chloride and related compounds as effective high-temperature cata-

lysts [16]. *Polymer-bound phase-transfer catalysis* ("triphase catalysis") has been studied [17], [18] and used in fixed-bed reactors [19]. The commercial potential of these catalysts lies in their ease of separation from the product.

Choice of Catalyst. Quaternary salts are generally the catalysts of choice, except in certain cases, such as the transfer of certain metal species or at higher temperature. In these cases, TDA-1, 18-crown-6, poly(ethylene glycol), or *N*-alkyldimethylaminopyridinium salts may be effective.

4. Industrial Aspects

The *advantages* of PTC are high yields, milder reaction conditions relative to classical conditions, and increased reaction rates. This results in higher reactor turnover; more reproducible and reliable processes; better control of temperature for enhanced safety; and, often fewer impurities, less waste, and fewer recycle streams. The use of PTC usually alleviates the need for anhydrous polar aprotic solvents. A broad range of solvents may be chosen for a PTC process. Selection of the appropriate solvent can be based on properties such as good recoverability, low flammability, low toxicity, and environmental considerations. Approximately one-third of PTC applications use sodium hydroxide as a base to replace the classical alkoxides, amides, and hydrides. Aqueous sodium hydoxide is less corrosive, does not add organic materials to the waste stream, is inexpensive, and is readily available. Special precautions, such as maintaining anhydrous conditions, are not necessary with PTC. Because of the two-phase nature of most PTC reactions, separation can often be performed easily by decantation. Catalyst recovery and recycle have been achieved for many PTC processes.

The *limitations* of PTC for industrial processes relate to the catalyst. Quaternary ammonium and phosphonium salts usually decompose at ca. 120 – 150 °C, and even lower in the presence of bases or certain nucleophiles. The two major modes of quat decomposition are Hofmann degradation and nucleophilic attack. Separation, recovery, and recycle of the catalyst from the product may be difficult. Other attributes of various catalysts that may represent disadvantages include cost, toxicity, and lack of local waste treatment capability.

5. Uses

5.1. Nucleophilic Displacement

The primary strength of PTC is the ability to react anions of many types with organic substrates. Most of the applications of anions in organic chemistry involve nucleophilic attack in general and nucleophilic displacement in particular. The following are representative examples of reactions described in the patent literature, some of which are currently on-line in commercial manufacturing processes.

Polymers. The commercial production of many polymers involves the attack of a difunctional oxygen nucleophile on a difunctional electrophile. Bisphenol A has been reacted under PTC conditions with a variety of electrophiles to prepare polycarbonate, polyester, polyether, epoxy resin, polyethersulfone, and the polyetherimide monomer [20–23] (see Fig. 4). These reactions are good examples of nucleophilic displacement (nucleophilic aromatic substitution, nucleophilic aliphatic substitution, and acylation) and represent the largest volume of commercial PTC applications. Phase-transfer catalysis offers many advantages for polymerization. Among them are the ability to achieve high molecular masses; the ability to achieve nonstoichiometric results by using stoichiometric quantities (stoichiometry is regulated by the quantity of the quaternary cation – anion pair in the organic phase); the ability to obtain polymers with >99 % electrophilic end groups (particularly useful for production of block copolymers); and the ability to obtain polydispersities well below 2.

Polymers may be *modified* under PTC conditions. For example, glycidyl azide polymer (solid rocket fuel) may be made from polyepichlorohydrin and azide [24]. Tributylamine serves as an in situ phase-transfer catalyst for the preparation of a poly(vinyl chloride) plasticizer [25].

Figure 4. Examples of polymerizations catalyzed by PTC

Pharmaceuticals and Agrochemicals. The pharmaceutical and agrochemical industries utilize PTC for many processes, among which alkylation of carbon, nitrogen, oxygen, or sulfur is the most widespread.

Pharmaceuticals. One of the most outstanding projects with PTC involves the Merck *chiral alkylation* and related reactions (see Fig. 5) [26]. A chiral phase-transfer catalyst was also used to perform a chiral Michael addition [27]. Another group employed a cinchona alkaloid for the preparation of amino acids in $> 99\,\%$ e.e. (enantiomeric excess), via alkylation of an activated imine followed by hydrolysis and recrystallization [28]. *N-Alkylation* is another important reaction in the pharmaceutical industry. Dozens of nitrogen-containing heterocycles have been alkylated under PTC conditions, ranging from the very lipophilic dibenzazepine [29] to the very hydrophilic pyrimidine bases [30].

Figure 5. Chiral alkylation

Esterification of penicillin derivatives may have been one of the first commercial pharmaceutical applications of PTC [31]. Esterification of estradiol has been patented on a 9-kg scale [32]. A precursor to acemetacin is prepared in very high yield by esterification [33]. Nucleophilic attack is the primary reaction in the condensation of benzaldehyde with glycine to form higher amino acids [34]. Nucleophilic aromatic substitution has been used to prepare 4-nitrophenetole [35].

Three consecutive PTC reactions (esterification, *C*-alkylation, and hydrolysis) are used to convert phenylacetic acid derivatives to compounds such as ibuprofen and naproxen [36]. *Short-lived radioisotopes* may be synthesized by using PTC, because in these cases, high yields and particularly rapid workup procedures are required. For example, methylation of an activated imine with $^{11}CH_3I$ followed by oxime formation and hydrolysis yields a highly specific radiolabeled amino acid with a total synthesis and workup time of 35 min [37].

Agrochemicals. Pyrethroid insecticides have been prepared by PTC *esterification* [38]. Halohydroxypyridines and pyrimidines have been *alkylated* [39] and *phosphorothiolated* [40]. *Fluorination of aromatic rings* is an important nucleophilic substitution in both agrochemicals and pharmaceuticals. Aromatic fluoride – chloride exchange has been demonstrated under PTC conditions [41] (most likely mass-transfer limited). Another example of nucleophilic aromatic substitution is preparation of the insecticide intermediate cyanotetrachlorobenzene by $CN - NO_2$ exchange [42]. Mono-*O*-alkylation of catechol has been achieved under PTC conditions [43].

5.2. Dehydrohalogenation

Phase-transfer catalysis has been used for the production of chloroprene by dehydrohalogenation in cascade reactors; the feed rate was 4310 kg/h [44]. Poly(vinyl chloride) has been dehydrochlorinated under PTC conditions [45]. *N*-Vinylcarbazole monomer has been produced by two PTC reactions: *N*-alkylation of carbazole by dichloroethane, followed by dehydrochlorination [46]. The agrochemical intermediate 3,5-dichloro-α-methylstyrene has been prepared by dehydrobromination of the corresponding α-bromoalkyl compound [47].

5.3. Oxidation – Reduction

In a classic paper [48] and patent [49], Lee and Freedman described the oxidation of primary and secondary alcohols and amines to aldehydes, ketones, and nitriles, respectively, by using hypochlorite and PTC. Alper and co-workers have performed many oxidations and related reactions by combining PTC with organometallic catalysis [50]. Selective reduction with dithionite under PTC conditions has been reported [51]. A combination of PTC and transition-metal chemistry has been patented to oxidize toluene to benzoic acid in $>99\,\%$ yield and purity by using atmospheric oxygen as the oxidant [52].

Others. The wide applicability of PTC to sometimes surprising reactions is illustrated by the following examples: free-radical polymerization [53], scission of polysulfide cross-links in the reclamation of rubber [54], Wittig reaction in the presence of 50 % sodium hydroxide [55], decomposition of polychlorinated biphenyls in transformer oil [56], and by the use of membranes in PTC [57]. Phenol can be removed from dilute aqueous waste streams by extraction of the phenoxide and reaction with benzoyl chloride in a continuous reactor – settler system [58]. Cyanation has been patented for the preparation of dyes [59] and *C*-alkylation has been used to augment the aroma of perfume compositions [60].

1. Introduction

Phenol is the specific name for hydroxybenzene, C_6H_5OH *[108-95-2]*. It is the generic name for any molecule containing one or more hydroxyl groups attached to an aromatic ring. Phenol was discovered in 1834 by Runge, who isolated it from coal tar and named it carbolic acid. In 1841 Laurent obtained it in crystalline form, determined its composition, and named it phenolic acid, which was later abbreviated to phenol. Finally Kekule formulated its molecular structure in 1858. Till the end of the 1800s all phenol was recovered from coal. It was mainly used as a disinfectant. In 1897 Hoffmann was the first to synthesize acetylsalicylic acid, the active ingredient in Aspirin, from phenol in a pure and stable form. In the 1900s demand for phenol grew with the commercialization of the phenolic resins after World War I, bisphenols after World War II, and polycarbonates during the 1960s. The first synthetic phenol was produced commercially by the benzenesulfonate process. Nowadays more than 95 % of phenol, around 7.3×10^6 t in total in 2003, is produced by the cumene oxidation process, and the rest is produced via toluene oxidation or recovered from coal tar. A direct process for oxidation of benzene to phenol has still not been commercialized.

2. Physical Properties

Phenol has a melting point of 40.9 °C. At lower temperatures it crystallizes as a white mass. In the molten state it is a clear, colorless liquid. The melting and solidification point of phenol is lowered considerably by traces of water (see Fig. 1).

At temperatures up to 68.4 °C it is partially miscibile with water [1] (see Fig. 2).

Phenol is soluble in most organic solvents, for example aromatic hydrocarbons, alcohols, ketones, ethers, acids, and halogenated hydrocarbons. It is less soluble in aliphatic hydrocarbons. Phenol forms azeotropic mixtures with water and other substances [2] (see Table 1).

Phenol has the following physical properties [3–6]:

M_r	94.11
bp (101.3 kPa)	181.75 °C
mp	40.9 °C

3. Chemical Properties

The chemical properties of phenol are characterized by the mutual influence of the hydroxyl group and the aromatic ring upon each other.

Figure 1. Effect of water on the solidification point of phenol

Figure 2. Miscibility of phenol and water

Reactions Involving the O–H Bond. In contrast to aliphatic alcohols phenol is a weak acid and therefore reacts with strong bases to form salts which are soluble in water. This effect is used to recover phenol from organic liquids such as coal tar. The pK_a value in aqueous solution is 10.0. The phenolate anion is stabilized by the aromatic ring system. At room temperature phenol can be liberated from the salts even with carbon dioxide. At temperatures near the boiling point of phenol, it can displace carboxylic acids such as acetic acid from their salts, whereby phenolates are formed. The hydoxyl group can easily be esterified (e.g., to phenyl acetate) and etherified (e.g., diphenyl ether).

Reactions of the Aromatic Ring. The acidity of phenol is due to the fact that the unshared electron pair is delocalized over the aromatic ring and thus stabilized [7].

Table 1. Azeotropic mixtures with phenol

Second component	Pressure, kPa	bp, °C	Proportion of phenol, %
Water	101.3	94.5	9.21
	70.8	90.0	8.29
	39.2	75.0	7.2
	16.9	56.3	5.5
Isopropylbenzene	101.3	149	2
n-Propylbenzene	101.3	158.5	14
α-Methylstyrene	101.3	162	7

The excess of electrons in the aromatic ring at the *ortho* and *para* positions makes phenol very susceptible to electrophilic substitution. An example is the reaction with bromine in aqueous solution to give 2,4,6-tribromophenol in high yield. Another important reaction is the coupling of carbon dioxide with sodium phenoxide at 125 °C to give the sodium salicylate (Kolbe reaction). At 125 °C carbon dioxide is substituted in the *ortho* position, whereas at temperatures above 250 °C the *para* isomer is favored. Other reactions following electrophilic substitution are chlorination, sulfonation, and nitration.

Liquid-Phase Oxidation. The oxidation of organic substances by molecular oxygen leads to a large number of intermediate products, for example, cumene hydroperoxide. These processes proceed with a complex radical mechanism [8]. Phenol acts as an inhibitor in such reactions by reacting with free radicals to form phenoxy radicals. These are relatively stable radicals which do not propagate the chain mechanism. Therefore any unwanted ingress of phenol into such oxidation processes must be avoided.

4. Production

Today the oxidation of cumene (Hock process) is by far the dominant synthetic route to phenol with a production rate of more than 6.7×10^6 t/a of phenol and about 4.1×10^6 t/a of the coproduct acetone. It is the most competitive process, supported by the demand for acetone. As the demand for phenol may increase more strongly in the future, there is still a commercial interest in finding new, coproduct-free routes to phenol, for example, the direct oxidation of benzene to phenol. The oxidation of toluene with benzoic acid as intermediate product is used for phenol production with an annual production of about $300\,000 \times 10^6$ t. About $300\,000 \times 10^6$ t of phenol is still recovered from coal tar. Since ca. 1995 the direct oxidation of benzene to phenol with nitrous oxide has been developed by Solutia but has still not been commercialized. Classic synthetic routes such as the benzene sulfonation process and hydrolysis of chlorobenzene with caustic soda no longer have any economic importance.

4.1. Cumene Oxidation (Hock Process)

General Overview. The process consists of two fundamental chemical reactions: cumene is at first oxidized with oxygen to cumene hydroperoxide (CHP). CHP is then cleaved to phenol and acetone by using a strong mineral acid as catalyst. Both reactions are very exothermic with heats of reaction of -117 kJ/mol for the oxidation of cumene and -252 kJ/mol for the cleavage of the peroxide.

These reactions were first reported in 1944 by H. Hock and S. Lang [9]. The industrial cumene oxidation process was developed and commercialized after World War II by The Distillers Co. in Great Britain and the Hercules Powder Company in the USA [10, 11]. The first plant started up in 1952 at Shawinigan, Canada, with a capacity of 8000 t/a. Today the biggest producers of phenol using cumene oxidation are INEOS Phenol (Europe and USA), Sunoco (USA), Mitsui (Japan, Singapore), Shell (USA), Polymeri Europa (Italy), and Ertisa (Spain). Some developed their own technology. Others use a licensed

Figure 3. Production of phenol from cumene

process from, for example, Kellogg Brown and Root or UOP. Although all use the principles of the Hock synthesis, there are differences in the technical design of the reaction and fractionation sections. The key item for the overall process yield is the formation of the byproducts dimethylbenzyl alcohol (DMBA) and acetophenone (ACP) in the oxidation step. ACP leaves the process with the high boilers from distillation. DMBA is dehydrated in the cleavage stage to α-methylstyrene (AMS), which partially forms high-boiling dimers and cumylphenols in the acid-catalyzed process step. The unconverted AMS is hydrogenated back to cumene later in the process.

The flow sheet of the cumene oxidation process is shown in Figure 3. The oxidation of cumene as the first reaction step is usually carried out in a series of bubble column reactors R1 and R2. Fresh and recycle cumene are fed to the first reactor. Oxygen is used in each reactor as oxidant. The bubble columns are operated at pressures ranging from atmospheric to about 700 kPa and temperatures in the range 80 – 120 °C. The temperature is controled by internal or external heat exchangers [12]. The final CHP concentration varies typically from 20 to 40 % [13]. The off-gas from the reactor is purified by two-step condensation of organic components with cooling water in condensers X1, X2 and chilled water or other refrigerants in X3. The organic components are mainly cumene and methanol besides some smaller amount of water. The residual impurities in the off-gas are finally removed in activated carbon adsorbers A1, A2. Layers of different types of activated carbon may be used for better co-adsorption of cumene and methanol [14]. The condensed cumene is recycled to the oxidation reactors. The CHP concentration in the oxidation product is increased by vacuum distillation in column VC to about 65 – 90 %.

The first part of the cleavage section is a series of heat exchangers R3, R4 within a circulation loop. Heat exchangers are used as reactors because the reaction is very fast and exothermic. The CHP is spontaneously diluted in the circulation product, which consists of phenol, acetone, cumene, and several byproducts as well as residual amounts of CHP. Normally sulfuric acid is used as the catalyst at a concentration of several hundred parts per million by weight (wppm). As the acid is completely dissolved in the reaction mass this type of process is called homogeneous cleavage. The temperature is in the range 40 – 80 °C at atmospheric pressure. The product from the first step, so-called cleavage product, is heated in R5 to temperatures above 100 °C. In this second step residual CHP is cleaved, as is the intermediate dicumyl peroxide (DCP), which is formed in the first step by condensation of CHP and DMBA. Finally residual DMBA is dehydrated to AMS and water. The product is cooled and neutralized with aqueous sodium phenolate NaPh. An aqueous phase is formed containing sodium sulfate and salts of organic acids. The aqueous phase is separated in neutralization drum V1 and sent to wastewater treatment.

The organic phase, consisting of phenol, acetone, cumene, AMS, dissolved water, and low- and high-boiling byproducts, is separated in a series of distillation columns.

More details on several process steps follow.

Oxidation. The oxidation of cumene with oxygen in the liquid phase proceeds by a complex radical mechanism [15]. The reaction is autocatalyzed by cumene hydroperoxide. Thus, the reaction rate to CHP not only depends on the cumene but also on the CHP concentration. Phenol is a strong inhibitor, so any recycled cumene must be treated to remove even traces of phenol. Formation of the byproducts DMBA and ACP depends on the CHP concentration [16, 17]. The activation energy for these side reactions are higher than for the main reaction. Thus, the oxidation should be run at low temperatures to suppress the formation of DMBA and ACP.

As the reaction rate depends on the CHP concentration, backmixed reactors are preferred for cumene oxidation to give high CHP concentrations. Bubble columns, in which the liquid phase is well backmixed, are therefore suitable for this process. On the other hand, high CHP levels cause more DMBA formation. Thus a series of several bubble columns is the optimal reactor concept [17].

The oxidation is operated either under overpressure at temperatures between 90 and 120 °C, or under atmospheric pressure at temperatures below 100 °C. Depending on temperature, the residence time in the oxidizer train is between 4 and 20 h [18]. Hattori et al. [19] investigated the influence of the partial pressure of oxygen on the reaction rate to CHP. As a rule of thumb, the partial pressure of oxygen in the gas phase should be above 0.1 bar for temperatures around 100 °C to ensure sufficient mass transfer and thus avoid hindrance of the reaction rate. This is an important issue because atmospheric oxygen is consumed from ca. 21 vol % to some residual value at the top of the bubble column. Thus, depending on the absolute pressure, the oxygen partial pressure also decreases but should not fall below the above-mentioned value. Lower temperatures than 100 °C may require lower partial pressures of oxygen. The oxidation of cumene with pure oxygen in stirred vessels has been already described [11].

In the early years of the cumene oxidation process, the oxidation was carried out as a three-phase reaction [20–22], so-called wet oxidation. In addition to cumene and air an aqueous sodium carbonate solution was continuously added to the reactors to extract and neutralize organic acids, which are formed during oxidation. Phenolchemie, now INEOS Phenol, was the first to operate the reactors without adding any caustic soda or sodium carbonate [23], a process known as dry oxidation.

CHP is a relatively stable organic peroxide. Nevertheless the thermal decomposition of CHP is the main source for DMPC formation in the oxidation process. Especially in large reactors the exothermic decomposition of CHP has to be taken into account during a shutdown when the reactors are not mixed by aeration. The reactor must be cooled down to below the self-accelerating decompositon temperature (SADT). Below the SADT heat removal by heat losses is higher than heat production by thermal decomposition, so that the reactor will not heat up [17, 24].

Concentration is performed by one- or multiple-step vacuum distillation [11]. Cumene is separated from concentrated CHP at temperatures below 100 °C to minimize thermal decomposition of the organic peroxide. As traces of organic acids are present in the overheads the cumene must be washed with aqueous caustic soda or sodium carbonate before it is recycled to the oxidation. To minimize any acid-catalyzed decomposition of CHP in the concentration step, fresh cumene is taken as reflux [25].

Cleavage. The first stage of homogeneous cleavage is performed either in a circulation loop with one or more heat exchangers in series, as shown in Figure 3 [26–28] or in a backmixed vessel with internal or external cooling devices [18, 29] (see Fig. 4).

In the backmixed vessel with internal cooling the temperature is, for example, maintained by vaporizing and refluxing acetone (Fig. 4a). Recycle acetone from the distillation is added to the CHP before the reaction vessel [11]. Another possibility is to remove the heat from the reaction vessel with an external heat exchanger in a loop (Fig. 4b).

Figure 4. Cleavage of cumene hydroperoxide (CHP) in backmixed vessels
A: Removal of heat by vaporizing and refluxing acetone;
B: Removal of heat by external cooling

In heterogeneous cleavage the first stage is carried out in a circulation loop of 40 wt % aqueous sulfuric acid [11, 30, 31] (Fig. 5). The heat is removed by a series of heat exchangers in the loop. Cumene hydroperoxide (CHP) from the concentration step is added to the acid on the suction side of the circulation pump in a ratio of 1:4. After the last cooler the organic phase is separated from the aqueous acid, and the acid is recycled to the pump.

Figure 5. Heterogeneous cleavage of cumene hydroperoxide (CHP)

The homogeneous cleavage of CHP to phenol and acetone is first-order both in CHP and in acid [32]. Only small amounts of acid are continuously added to the reactor. The acid activity is considerably dependent on the solvent system [13]. Especially the amount of dissolved water, which is formed by dehydration of dimethylbenzyl alcohol (DMBA), has a major influence on the acid activity [33]. In the first stage of cleavage CHP partially condenses with DMBA to form the intermediate dicumyl peroxide (DCP) and water [29]. Other byproducts are hydroxyacetone from the reaction of CHP with acetone, 2-methylbenzofurane from the reaction of hydroxyacetone with phenol, diacetone alcohol from the aldol condensation of acetone, and *mesityl oxide* from the dehydration of diacetone alcohol. An overview of these reactions is given in [34].

The product from the first cleavage stage contains residual amounts of CHP and DMBA as well as the intermediate DCP. The reaction is completed in a short-residence-time plug-flow reactor in the second stage of the cleavage (see Fig. 3). The product is heated to temperatures above 100 °C [27, 29, 35]. DCP and water react back to CHP and DMBA, CHP is cleaved spontaneously to phenol and acetone, and DMBA is completely dehydrated to α-methylstyrene and water.

After cooling, all reactions are stopped by adding a neutralizing agent such as aqueous sodium phenolate to the cleavage product (see Fig. 3). Salts from the neutralization are extracted with the aqueous phase. It is important to neutralize the sulfuric acid and the organic acids to avoid corrosion in the distillation stage. On the other hand, salts from the neutralization should be extracted thoroughly with the aqueous phase to avoid fouling and plugging of the evaporators in distillation. Another possibilty is to neutralize the cleavage product on a caustic-exchanged sulfonic ion-exchange resin [13, 36].

Distillation. In the first distillation column C1 (see Fig. 3), acetone is separated as the top product. This acetone stream contains mostly water and low boiling aldehydes as impurities. For high-purity acetone, the top stream must be separated in an additional reactive distillation column [37]. Caustic soda is introduced over the feed position in this reactive distillation column. The caustic soda catalyzes condensation reactions of the aldehydes to form high boilers. A side stream above the feed contains pure acetone. The top stream of this column is recycled back to the cleavage. Cumene and AMS are taken as overheads in column C2. In column C3 the cumene – AMS fraction is separated into cumene as a top product and crude AMS as the bottom stream. This crude AMS can be further purified to obtain pure AMS. The top product contains mostly cumene and some AMS. This stream is sent to the hydrogenation, where AMS is hydrogenated to cumene. The hydrogenation takes place in fixed-bed reactor R6. After removal of residual phenol by extraction with caustic soda (cumene scrubber

V2), the reactor outlet is recycled back to oxidation. The aqueous sodium phenolate from the cumene scrubber is used as neutralization agent for the cleavage product. Pure phenol is taken as the overhead from column C4. The bottom stream of column C4 consists mainly of acetophenone, AMS dimers, cumylphenols, and tar and may be disposed of by incineration. In older processes the tar is treated thermally to recover cumene, AMS, and phenol [11]. A new application is the use of the desalted tar for production of carbon black [38]. Several minor impurities which are formed in cleavage, such as hydroxyacetone and mesityl oxide, can not be easily separated from phenol by simple distillation. For ultrahigh-purity phenol some subsequent purification steps are needed. The phenol from the top stream of column C4 can be treated with an acidic ion exchange resin in a fixed-bed reactor in the fluid phase. This catalyzes reactions of ketones and aldehydes. These reactions generate low and high boilers, so that further distillation columns are needed to finally obtain pure phenol [39]. As an alternative the phenol can be separated from impurities by extractive distillation [40, 41]. Polyalkylene glycol, alkanediols, and ethanolamines are used as extractive agents. The extractive agent is introduced in a first column above the feed. The interaction between the phenol and the extractive agent results in their being in the bottom stream. The impurities leave the column over the top stream. A second column is used to separate the extractive agent from the pure phenol. Water can also be added to enhance the separation of minor impurities [42]. Another possibility for the purification of the phenol stream is to add amines [43]. The amine reacts in a first step with the ketones and in a second step with aldehydes to high boilers that can be easily separated from phenol by distillation.

4.2. Toluene Oxidation

General Overview. In the 1950s it appeared that toluene would be available in large quantities and it would be a cheaper source for the aromatic ring than benzene. One suggestion was to use toluene for the production of phenol. This process was developed by the California Research Corp. [44] and Dow Chemical [45]. The two-steps of the process are first the oxidation of toluene to benzoic acid, which was already well known, and second the oxidation of benzoic acid to phenol. In principle the conversion of toluene to phenol is a complete oxidation of the methyl group with the byproducts carbon dioxide and water.

The oxidation of toluene as the first step is carried out in the liquid phase at temperatures about 100 – 150 °C and a gauge pressure of about 2 bar [46–48].

Atmospheric oxygen is used. A cobalt naphthenate is used as a soluble catalyst at concentrations between 0.1 and 0.3 %. The oxidation of toluene to benzoic acid has a complex radical chain mechanism. Benzyl alcohol and benzaldehyde are intermediates in the successive oxidation to benzoic acid. Byproducts such as benzyl benzoate and biphenyl are formed, as well as formic acid, acetic acid, and, in smaller amounts, carbon dioxide and carbon monoxide [46, 47].

For the oxidation of benzoic acid as the second step molten benzoic acid is used as the reactant and solvent medium. The temperature is about 230 – 240 °C at atmospheric pressure [46–48]. Benzoic acid reacts with atmospheric oxygen, steam, and soluble copper(II) benzoate as catalyst [46, 49]. Magnesium salts may be added to act as a promotor [50]. The formation of phenol is the net result of several reactions which occur simultaneously in the system. Copper(II) benzoate thermally decomposes to copper(I) benzoate and benzoylsalicylic acid:

The copper(I) benzoate from the first reaction step is regenerated with atmospheric oxygen:

In the presence of water or steam, benzoylsalicylic acid is hydrolyzed to benzoic acid and salicylic acid:

The benzoylsalicylic acid is decarboxylated rapidly to give phenol and carbon dioxide:

Thus, the net reaction for the oxidation of benzoic acid is:

Byproducts include benzene and diphenyl ether.

Dow Process. The first commercial plant based on the Dow process was started up in the early 1960s at Landar, British Columbia, operated by Dow-Canada (shut down), and the second at Kalama, Washington, operated by Dow Chemical Company (capacity in 2002 ca. 32 000 t/a phenol). The third plant was built at Rosenburg, Netherlands, operated by DSM (capacity in 2002 ca. 110 000 t/a phenol). In 1991 a new plant was brought on line in Japan by Nippon Phenol (capacity in 2002 ca. 120 000 t/a phenol).

Simplified process flow diagrams of the Dow process are given in [46–48, 51, 52]. Figure 6 gives an overview of the process. Fresh and recycle toluene as well as air and the cobalt catalyst are charged to gas – liquid reactor R1, which can be, for example, a bubble column. The reactor has cooling devices to remove the reaction heat, for example, in an external circulation loop as shown in Figure 6. The toluene conversion is limited to 40 %. The yield of benzoic acid is about 90 %. The off-gas from the reactor is cooled by passing it through a water-cooled condenser. The condensed toluene is recycled to the reactor, and the water phase is withdrawn for further wastewater treatment. The noncondensable gas, principally nitrogen, is treated in activated-carbon adsorption unit A1 to remove traces of toluene and other organic components. The liquid phase from the reactor is at first fractionated in column C1. Toluene and the intermediate benzaldehyde are taken overhead for recycle. The crude benzoic acid as the bottom product is purified in the second column C2. The catalyst containing high boilers (tar) is taken as the bottom product, which is partially recycled to the reactor.

Purified benzoic acid is oxidized in the second reactor R2, which is a stirred gas – liquid reactor. In the presence of the copper(I/II) catalyst the acid is contacted with air and recycled vaporized water. In addition steam may be added to the air. Small amounts of magnesium benzoate may be added as a promoter. The benzoic acid conversion is 70 – 80 % with a yield of phenol of about 90 %. Phenol, benzoic acid, water, and other organic components are vaporized continuously. The vapors are charged to column C3. Water and hydrocarbons are taken as the overhead fraction and separated into two liquid phases. The remaining gas phase is purified in adsorption unit A2. The separated water is used to extract benzoic acid from the tar which has to be removed from reactor R2. This is done in extraction unit V1, which consists of a series of several mixer – settlers. The aqueous phase from V1 is vaporized and recycled to reactor R1. The

Figure 6. Production of phenol from toluene
R1 toluene oxidation reactor; A1 adsorption unit; C1 toluene column; C2 benzoic acid column; R2 benzoic acid oxidation reactor; A2 adsorption unit; C3 crude phenol column; C4 benzene column; C5 pure phenol column; V1 tar extraction unit

tar contains the copper salts. If it is burned special incineration equipment is required to insure that no heavy metal emissions occur. The organic phase from the overheads of column C3 contains mainly toluene and benzene. Benzene is separated from toluene in column C4. Toluene is recycled to the oxidation reactor R1. Crude phenol is taken as a side cut from column C3. In Column C5 pure phenol is taken as the overhead. Benzoic acid is withdrawn as the bottom product and recycled to reactor R2. Because of the corrosive character of benzoic acid apparatus must be constructed from stainless steel 1.4571 or even from Hastelloy.

Lummus Process. In 1978 The Lummus Company announced a new process for the oxidation of benzoic acid [53]. The oxidation is conducted in the vapor phase over a copper-containing catalyst [54]. Instead of using a gas – liquid reactor (R2 in Figure 6), the reaction is conducted in a vapor-phase reactor on a heterogeneous catalyst; this is the main difference from the Dow process. Lummus announced that there is no formation of tars or nonvolatile residues. This is probably due to the fact that phenol is rapidly removed from the reaction zone. It is believed that the residues in the gas – liquid process are derived from phenol. As there is no need for tar treatment and incineration Lummus claims that the fixed investment is significantly lower for their process [53]. However, the process has not yet been commercialized.

4.3. Phenol from Coal

The recovery of "natural" phenol from coal is the oldest commercial process for producing phenol and it is still practiced. Nowadays, this process is only of little importance as a source of phenol.

Phenol, as well as many other aromatic compounds, is recovered from the vapors of coal carbonization (Fig. 7). Coal is heated to above 900 °C with the exclusion of air in a coke oven. Condensable hydrocarbons and gases are removed as vapors leaving coke as the solid residue. The vapors are condensed to form coal tar. The gas may be washed with aqueous sulfuric acid or phosphoric acid to recover ammonia. It can also be washed with a wash oil to further remove benzene. The remaining gas, which consists of hydrogen and methane, is used as a fuel on site [55].

The fractionation of coal tar is described in detail in [56]. The simplied process diagram shown Figure 7 is based on information about the Rütgers Process given in [57]. The coal tar is further processed by continuous distillation. In

Figure 7. Production of phenol from coal
R1 coke oven; C1 light oil/water column; C2 carbolic oil column; C3 naphthalene oil column; C4 anthracene oil column; E1 extraction unit; C5 hydrocarbon removal column; C6 precipitation column; C7 fractionation column

a first column C1 light oil, which contains benzene, toluene, and xylenes, is separated together with water. In the second column C2 carbolic oil, containing phenol and phenolic compounds, is taken as the overhead and naphthalene oil as a side cut. The bottom product from C2 is further fractionated in columns C4 – C6 to give wash oil for benzene recovery from the off-gas, methylnaphthalene oil, anthracene oil, and pitch. Plate columns or columns with random packings are used with high reflux ratios and a high degree of thermal integration.

The carbolic oil, which constitutes ca. 2 – 3 % of the coal tar, contains about 30 – 35% of phenolic compounds such as phenol and cresols. Other components are non-phenolic benzene derivatives and pyridine bases. The carbolic oil is treated with 8 – 9 % caustic soda in extraction unit E1. Phenol and cresols, which are known as tar acids, are extracted as salts into the aqueous phase, which is called phenolate lye. The organic phase is further treated to recover naphthalene by crystallization. The crude phenolate lye is treated by steam distillation in column C5 to separate residual hydrocarbons and pyridine bases. The phenolate lye is then treated with carbon dioxide to liberate the acid tars from their salts in column C6. The aqueous phase containing sodium carbonate is further treated to remove dissolved phenol. The organic phase is fractionated into pure phenol (*bp* 181.8 °C), *o*-cresole (*bp* 191.0 °C), a mixture of *m*- and *p*-cresoles (*bp* 202.0 – 203.0 °C), and a xylenol fraction (*bp* up to 210 °C) by batch distillation.

4.4. Other Processes

4.4.1. Sulfonation of Benzene

The production of phenol via sulfonation of benzene is the oldest process to produce synthetic phenol. It is based on research by Wurtz and Kekule in 1867, who found that heating sodium benzenesulfonate in molten sodium hydroxide gives sodium phenolate:

Sodium benzenesulfonate is produced by reaction of benzene with concentrated sulfuric acid to give benzenesulfonic acid and subsequent neutralization with sodium sulfite or sodium carbonate. Phenol is liberated from the sodium phenolate by treating the aqueous solution with carbon dioxide.

Phenol is no longer produced by this process, details of which can be found in [50, 51, 58].

4.4.2. Chlorination of Benzene

Alkaline Hydrolysis. DURANT and BARDY discovered in 1872 that the treatment of chlorobenzene with aqueous caustic soda affords sodium phenolate and sodium chloride.

Chlorobenzene is produced from benzene and chlorine. Typically the process was combined with chlor-alkali electrolysis to recover chlorine from the sodium chloride.

Raschig-Hooker Process. The reaction of chlorobenzene with steam to give phenol and hydrochloric acid was discovered by MEYER and BERGIUS in 1914. It was commercialized as the Raschig – Hooker process at BASF.

Chlorobenzene is produced via oxychlorination of benzene with hydrochloric acid and oxygen. Thus the hydrochloric acid is recycled and the process is therefore also called the regenerative Raschig process.

Details about these processes, in which phenol is made from the intermediate chlorobenzene, are given in [50, 51, 58]. They are no longer used for commercial production of phenol.

4.4.3. Direct Oxidation of Benzene

General. The direct oxidation of benzene would be the simplest process to produce phenol. For example, benzene can easily be oxidized by air, but the phenol which is formed is further oxidized much more easily than benzene. It reacts very fast with oxygen or any other oxidizing agent in successive reactions that finally form carbon dioxide and water. Therefore, the conversion of benzene must be limited to only a few per cent. Direct oxidation of benzene has not yet been used for commercial production of phenol. However several attempts were made since the mid-1990s to use nitrous oxide as the oxidzing agent in a heterogeneous gas-phase process.

Direct Oxidation with Oxygen or Hydrogen Peroxide. In [58] a survey is given on the first patents, granted in the 1920s and 1930s. For example, benzene can be oxidized to phenol with air in the gas phase at 600 – 800 °C without any catalyst. A commercial plant of Solvay Process Company using this process was operated between 1940 and 1947. In [59–61] an overview is given on the use of oxygen or hydrogen peroxide on different heterogeneous catalysts. With oxygen the selectivity of phenol formation with respect to benzene can reach more than 90 %, but only if the benzene conversion is limited to a few per cent. When hydrogen peroxide is used the conversion may reach more than 30 % with a selectivity of more than 95 %. Titanium silicalites (TS-1) are typically used as a catalysts for this. However, because of the high price of hydrogen peroxide, it is not economic to produce phenol in this way.

Direct Oxidation with Nitrous Oxide. The direct oxidation of benzene with nitrous oxide N_2O was mainly developed by Solutia, formerly Monsanto, in cooperation with the Boreskov Institute of Catalysis in Russia [62].

N_2O is a major component in the off-gas from adipic acid production plants. Solutia produces 400 000 t/a of adipic acid from cyclohexane [63], which is associated with the formation of about 200 000 t/a of nitrous oxide [59]. Nitrous oxide is a greenhouse gas and must be decomposed to avoid emission [64]. The use of nitrous oxide for the direct oxidation of benzene would therefore be ideally suited to any adipic acid producer.

The oxidation is carried out in the gas phase with zeolites of the ZSM-5 type as the heterogeneous catalyst. The heat evolved is 286 kJ/mol [61]. The reaction temperature is in the range between 300 and 450 °C at atmospheric pressure. The reaction time is 1 – 2 s. The conversion is up to 40 % with selectivities of benzene to phenol of more than 95 %. The space – time yield is 0.24 – 0.64 g phenol per gram catalyst per hour.

Figure 8. Production of phenol by direct oxidation of benzene with nitrous oxide
R1, R2 reactors; X1, X2 gas heaters; X3 benzene vaporizer; C1 benzene column; C2 phenol column

Byproducts are carbon dioxide and water from total oxidation, as well as higher boiling phenol derivates such as hydroquinone. Many patents deal with the preparation of the zeolite; a survey is given in [61]. Coking deactivates the catalyst after several hours. The catalyst can be regenerated by passing an oxygen-containing gas through the catalyst bed at elevated temperatures [62].

Based on the literature and patents a simplified process flow diagram was evaluated (Fig. 8). Reactor R2 is in operation while reactor R1 is regenerated. Fresh and recycle benzene is evaporated in heat exchanger X3. After adding nitrous oxide the gas is heated to 300 °C. An adiabatic process would limit the benzene conversion to about 10 %. Therefore, the reactors may have cooling devices, for example, external interbed exchangers. The off-gas is cooled to condense benzene, water, phenol, and higher boiling byproducts. The off-gas, consisting mainly of nitrogen and carbon dioxide, is purged. In the first column C1 benzene is separated and recycled. Phenol is taken as the overhead from the second column C2.

Solutia has operated a pilot plant at their site in Pensacola, Florida, first in 1996 [62]. It is not clear whether they used pure nitrous oxide or nitrous oxide from adipic acid off-gas. Nevertheless, there may be some problems with commercialization of the process. The construction of a new plant for 136 000 t/a of phenol was delayed to post 2002 [65].

5. Environmental Protection

Wastewater Purification. Because of its toxicity phenol must be removed from wastewater. Phenol is classified in the water-hazard class 2 (hazardous to water). For example, the wastewater from neutralization in the cumene oxidation process contains about 1 – 2 % phenol. The extraction of phenol from water with an aromatic solvent is well known. In [66] the performance of cumene, acetophenone, and mesityl oxide is compared. Other suitable solvents are a mixture of cumene and α-methylstyrene or a mixture of acetophenone and dimethylphenylcarbinol [67]. For example, the partition coefficient of phenol for cumene against water is about 1.5. For effective extraction a countercurrent process is used, such as a multistep mixer – settler system or an extraction column [68]. For nearly complete phenol removal the pH of the wastewater should be below 7 to release all phenol from sodium phenolate. In this way the phenol content in the wastewater can be reduced to some 10 ppm by weight. The remaining phenol is removed in the subsequent biological waste-

Table 2. Quality specifications for phenol

Pharmacopeia	Water content %	Color	Content, %	Nonvolatile impurities, %	Solidification point, °C
USP 26/2003	≤ 0.5		99.0 – 100	0.05	≥ 39.0
Ph. Eur., 4th ed., 2002		colorless, faintly pink, or faintly yellow	99.0 – 100	0.05	≥ 39.0
ASTM D 2439	≤ 0.1				≥ 40.6

Table 3. Quality specifications for acetone

Pharmacopeia	Water content, %	Density	Content, %	Nonvolatile impurities	Free acid (as acetic acid), %	Permanganate test, t/min
USP 26/2003		0.789	≥ 99.0	≤ 50 mg/kg		15
Ph. Eur. 4th ed., 2002	≤ 0.38	0.790 – 0.793		≤ 50 mg/kg		120
ASTM D 329	≤ 0.5	0.7910 – 0.793	≥ 99.5	5 mg/100 mL	0.002	30
DIN 53247	≤ 0.3	0.7900 – 0.792	≥ 99.5	1 mg/100 mL		
BS 509/1987	≤ 0.3	0.7890 – 0.791	≥ 99.5	5 mg/100 mL	0.002	180

water treatment. Other solvents used for the extraction of phenol from wastewater are butyl acetate, methyl isobutyl ketone, and diisopropyl ether, which are typically used in the recovery of phenol from gas condensates in gas production (Phenosolvan process). The removal of phenol from wastewater can also be carried out by adsorption on, for example, activated carbon.

Waste-Gas Purification. According to TA Luft phenol is classified in emissions class I [emission must be limited to a mass stream of 0.1 kg/h or a mass concentration of 20 mg/m^3 (STP)]. Phenol in gas streams can be removed by absorption. Aqueous caustic soda is used as the scrubbing agent. The absorption columns have several layers of random packings to improve mass transfer. Adsorption on activated carbon is another possibility for removing phenol from gas streams. Phenol, as well as other organic components, can be completely incinerated. Combustion devices for this treatment are thermal or catalytic incinerators [69] and flares.

6. Quality Specifications.

The quality specifications of the various pharmacopeias are generally met by synthetically produced phenol. These specifications are limited to identity tests, assays, determinations of acidically reacting impurities, nonvolatile impurities, color, water solubility, density, solidification point and water content. Quality specifications for phenol and the coproduct acetone are listed in Tables 2 and 3, respectively. The quality specifications of the various users of phenol go beyond these criteria to some extent. Impurities such as hydroxyacetone, mesityl oxide, 2-methylbenzofuran, and other carbonyl compounds can result in discoloration of downstream products in further processing. The content of lower carboxylic acids can increase the extent of undesired side reactions. Metal ions can damage catalysts or lead to discoloration of reaction products. The concentrations of these components in phenol must therefore be limited.

Synthetic phenol is normally colorless. Color is determined by comparison with calibrated color scales.

The solidification point of phenol is a sensitive criterion for impurities. It is, however, strongly affected by the water content (see Fig. 2). The effect of water on this method of testing can be excluded by the addition of gypsum or dry 4A molecular sieves. ASTM methods (D 2439-96, D 329, D 1363, D 1686-96, etc.) are used as the methods of investigation. Factory specifications of the producer and manufacturers are also used and are much stricter. Especially when phenol is used for Bisphenol A production it has less than 100 ppm impurities.

7. Storage and Transportation

Large quantities of phenol are transported as liquids in ships (with double walls) and road or rail tank cars, all of which are equipped with heating coils. Steel is generally used as the container

material. If the phenol is to remain colorless for as long as possible, the walls of the containers must be made of stainless steel. Pure phenol is therefore stored predominantly in stainless steel tanks, which are insulated to avoid heat losses. On storing liquid phenol it must be ensured that the temperature remains below 70 °C. The lower explosion limit for phenol – air mixtures is reached at a saturation temperature of 73 °C, corresponding to a phenol vapor fraction in the mixture of 1.3 vol %. At storage temperatures below 70 °C the tank gas volume is blanketed with nitrogen.

Smaller quantities of phenol are transported in steel drums. If the phenol contains water, steel drums are not suitable because of the coloration of the phenol which occurs. In this case drums of galvanized sheet metal are necessary.

For phenol the following transport regulations are in force:

Land transportation ADR/RID (cross-border/inland)	
ADR/RID	Class 6.1 (T1) toxic substances
UN No.	2312
Packaging group	II
Inland waterway transportation ADN/ADNR	
ADN/ADNR	Class 6.1

EMS No.	6.1–02

8. Uses and Economic Aspects

In 2003 about 7.3×10^6 t of phenol was produced. The total production capacity worldwide is more than 9×10^6 t. Around 37 % of global output, is used for the production of bisphenol A [70]. Bisphenol A is especially used for the production of high-grade polycarbonates for compact discs, for glazing, and for the automotive industry. Bisphenol A is also used for the production of epoxy resins. The second largest consumption of phenol is for the production of phenolic resins with formaldehyde. They are mainly used for underseal applications in the automotive industry. Phenol is also used for the production of caprolactam via cyclohexanol – cyclohexanone. Many other derivatives of phenol are produced, such as aniline, alkylphenols, diphenols, and salicylic acid. Table 4 shows the distribution of phenol capacity and demand in 2000 and 2003 and the forecast for 2007 and 2010 [70]. As the automotive industry is an important consumer of phenol derivatives such as polycarbonates and phenolic resins, the entire phenol demand still tends to be cyclical and closely tied to this market.

The dominant synthetic route is cumene oxidation, which accounts for about 95 % of the total phenol production. This process will maintain its leading position as long as a market exists for the coproduct acetone. Production from toluene oxidation and from coal each amount to about 300 000 t/a. Toluene oxidation is only economical at a low toluene price relative to that of benzene. The latest plant based on this technology was built in 1991 in Japan. This indicates that the economics of the toluene oxidation process are not competitive with the cumene oxidation process. As long as coal tar is used as the natural source for aromatics phenol will be recovered in this way, too. The classic synthetic routes such as sulfonation or chlorination of benzene are no longer used because of the formation of considerable quantities of sodium salts as byproducts. Commercial production of phenol by direct oxidation of benzene with byproduct nitrous oxide does not seem to be viable in the near future.

9. Toxicology and Occupational Health

Phenol occurs as a metabolic product of animals and humans in the blood, urine, and feces in free form as well as in conjugated form as a glucuronide and sulfate. Excretion via urine is the main elimination pathway of phenol metabolites. An estimated 100 000 t/a of phenol (metabolites) are released worldwide in human excrement [71].

Phenol is harmless in small quantities according to present knowledge. Because of its germicidal effect phenol was long used in the 1800s as a very effective disinfectant (carbolic acid, Lister spray). However, because of its protein-degenerating effect, it often had a severely corrosive action on the skin and mucous membranes.

Table 4. Worldwide production capacity and demand for phenol (in 1000 t/a)

	2000	2003	2007[a]	2010[a]
Production capacity from				
Cumene	7641	8490	9879	10079
Toluene	307	307	307	307
Coal tar	291	291	291	291
Total	8239	9088	10477	10677
Demand for				
Bisphenol A	2306	2678	3446	3864
Phenolic resins	2236	2419	2564	2709
Caprolactam	739	705	724	728
Others	1335	1454	1576	1686
Total	6616	7256	8309	8987

[a]Forecast.

Today phenol has only limited use in pharmaceuticals because of its toxicity.

Toxicology. Phenol is toxic in high concentrations. It can be absorbed through the skin, by inhalation, and by swallowing. The typical main absorption route is the skin, through which phenol is absorbed relatively quickly, simultaneously causing caustic burns on the affected area of skin. Besides the corrosive effect, phenol can also cause sensitization of the skin in some cases. Resorptive poisoning by larger quantities of phenol, which is possible even over small affected areas of skin, rapidly leads to paralysis of the CNS with collapse and a severe drop in body temperature. Skin that is wetted with phenol or phenolic solutions must therefore be decontaminated immediately. After removal of contaminated clothing, polyglycols (e.g., lutrol) are particularly suitable for washing the skin.

On skin contamination local anesthesia sets in after an initial painful irritation of the affected area of skin. Hereby the danger exists that possible resorptive poisoning is underestimated. If phenol penetrates deep into the tissue, this can lead to phenol gangrene through damage to vessels. The effect of phenol on the CNS, namely, sudden collapse and loss of consciousness, is the same for humans and animals. In animals a state of cramp precedes these symptoms because of the effect phenol has on motor activity controlled by the CNS.

Caustic burns on the cornea heal with scarred defects. Possible results of inhalation of phenol vapor or mist are dyspnea, coughing, cyanosis, and lung edema. Swallowing phenol can lead to caustic burns inn the mouth and esophagus and stomach pains. Severe, though not fatal, phenol poisoning can damage inner organs, that is, kidneys, liver, spleen, lungs, and heart. In addition, neuropsychiatric disturbances have been described after survival of acute phenol poisoning. Most of the phenol absorbed by the body is excreted in urine as phenol and/or its metabolites. Only smaller quantities are excreted with the feces or exhaled [72].

Acute Toxicity. Signs and symtoms of acute toxicity for animals and humans are similar independent of the route of administration. Absorption is rapid. Phenol can produce symtoms of toxicity within minutes. In animals the LD_{50} was determined for different species and forms of administration. For oral administration the following values are reported: mouse 500 mg/kg; dog 500 mg/kg; rabbit 420 mg/kg [73]. Concentrations of 200 and 20 ppm phenol in aqueous solution were administered to rats. The LD_{50} values determined were 340 and 620 mg/kg respectively [74]. In the summary and evaluation of data on the lethal dose for humans, a value of 140 mg/kg was reported as the minimum lethal oral dose [75].

Subacute to Chronic Toxicity. Repeated administration of phenol leads to neurotoxic, immunotoxic, nephrotoxic, and hepatotoxic effects, as well as changes in hematological parameters [72].

Carcinogenicity. The published reports on the carcinogenic and cocarcinogenic investigations give ambiguous indications [72]. According to EU criteria on carcinogenic potential, there is neither need for classification and labeling nor for further investigations.

Mutagenic Effects and Reproductive Toxicity. According to TRGS 905 (the German technical regulations for handling hazardous substances, 10/2002) phenol is classified as a class 3 mutagen. The discussion whether phenol should be classified as a mutagen or not is still on-going.

Occupational Health. The following limiting values (8 h time-weighed average) were laid down for work protection (2003):

FI, ES, UK	20 mg/m^3
D, B, F, CH	19 mg/m^3
USA (NIOSH/OSHA AGGH):	19 mg/m^3
NL	8 mg/m^3
AU, IR, IT	7.8 mg/m^3
S, DK, NO	4 mg/m^3

Short-term exposure levels:

FI, UK	38 mg/m^3
D, CH	19 mg/m^3
S	8 mg/m^3

Phenol exposure can be determined from the phenol concentration in urine. The permitted BAT value is 300 mg/L.

Classification According to the EU Directives/Ordinance on Hazardous Materials. Phenol is classified with the hazard symbols T (toxic) and C (caustic) and must be labeled with the R phrases R24/25 (toxic in contact with skin and if swallowed) and R 34 (causes burns). Phenol-containing formulations require the following labeling, depending on the concentration c:

$5\,\% < c$	T, R24/25–34
$1 < c < 5\,\%$	Xn, R21/22–36/38

1. Alkylphenols

Helmut Fiege and Heinz-Werner Voges

In this article alkylphenols are defined as monohydric phenols in which one or more ring hydrogen atoms have been replaced by the same or a different alkyl, alkenyl, cycloalkyl,

cycloalkenyl, or aralkyl group, but which have no other substituents. Indanols are treated as disubstituted alkylphenols. For cresols and xylenols, see ⟶ Cresols and Xylenols.

In the nomenclature, alkylphenols are usually considered as phenol derivatives; the alkyl groups are ordered alphabetically and numbered starting from the hydroxyl group. In industry, products from cresol or xylenol are often described as derivatives of the corresponding cresols or xylenols, e.g., 6-*tert*-butyl-2,4-dimethylphenol is called 6-*tert*-butyl-2,4-xylenol. A very complicated system which is, e.g., found in handbooks considers alkylphenols as benzene derivatives. Here, the substituents are ordered alphabetically, and numbered such that the sum of all numbers gives the smallest possible value. 6-*tert*-Butyl-2,4-dimethylphenol is thus referred to as 1-*tert*-butyl-2-hydroxy-3,5-dimethylbenzene. According to this system cresol derivatives are also occasionally described as toluene derivatives, e.g., 2,6-di-*tert*-butyl-4-methylphenol is called 3,5-di-*tert*-butyl-4-hydroxytoluene (BHT). Some alkylphenols have common names.

1.1. Physical Properties

Pure alkylphenols are colorless liquids or form low-melting crystals, which frequently darken with time. They show a tendency to supercooling. Within groups of substitutional isomers the para isomers have the highest melting points. In some cases two melting points are observed (occurrence of a metastable phase).

The boiling points are > 200 °C at normal pressure and increase with molecular mass. Whereas the boiling point difference between meta and para isomers is very small, the para compounds usually boil 10 – 20 °C higher than the isomeric ortho compounds. The sharper rise in boiling point on para substitution remains if more alkyl groups are present. A particularly sharp rise in boiling point results if a 3- or 5-alkylphenol is *tert*-butylated in the 4-position [6]. This effect is used industrially for the separation of alkylphenols which cannot be separated by distillation.

The relatively small rise in boiling point on ortho substitution is caused by steric hindrance of hydrogen bond formation. This steric hindrance is reflected in many other physicochemical properties of alkylphenols (e.g., spectra, dissociation energies, acidity of the O – H bond, association, dipole moments [7], [8]).

Physical properties of individual alkylphenols are listed in the corresponding sections. Further data for ethylphenols can be found in [9], for isopropylphenols in [10-13], and for *tert*-butyl- and other phenols in [14-16]. Vapor pressure curves for many alkylphenols are given in [17] and thermochemical data under normal conditions in [18]. The relationship between vapor pressure and association of alkylphenols is given in [19].

Alkylphenols are readily soluble in polar organic solvents (lower alcohols, ketones, esters, carboxylic acids); their solubility in hydrocarbons increases with the number and size of the alkyl substituents on the ring. The opposite trend occurs with regard to solubility in water, higher alkylphenols are virtually insoluble and lower alkylphenols are soluble in water only at increased temperatures to a noticeable extent. Their water-solubility shows a temperature-dependence similar to that of phenol, but, with considerably higher critical solution temperatures (i.e., the temperature where unlimited miscibility with water occurs) [20], [21]. Within a group of substitutional isomers the water-solubility decreases with increasing proximity of the alkyl substituents to the hydroxyl group. The presence of other water-soluble organic compounds increases the solubility of alkylphenols and lowers the critical solution temperature [22].

Water can have considerable solubility in alkylphenols [20], [21] and hydrates may be formed, e.g., 6-*tert*-butyl-3-methylphenol, $C_{11}H_{16}O \cdot 1/4\ H_2O$, *mp* 37 °C [15].

1.2. Chemical Properties

The chemical behavior of alkylphenols deviates from the reactions typical of phenol with increasing number, size, and degree of branching of the alkyl groups. This change in properties is particularly pronounced in 2,6-di-*tert*-alkylphenols [23]. The alkyl groups themselves can also show typical reactions.

Acidity. Alkylphenols are less acidic than phenol. The acidity decreases in the direction of meta > para > ortho substitution. The decrease in acidity due to the presence of ortho alkyl groups becomes more pronounced the more these groups are branched in their α-positions. This is mainly because of steric hindrance of solvation in the phenolate anion formed [7].

These effects are reflected in the solubility of alkylphenols in alkali: 4-*tert*-butylphenol, 2-isopropylphenol, 2,6-diethylphenol, 4-*tert*-butyl-2,5-dimethylphenol, and 4-*tert*-butyl-2,6-dimethylphenol are soluble in dilute aqueous sodium hydroxide solution, 2-*tert*-butyl-4-methylphenol, 6-*tert*-butyl-2,4-dimethylphenol, 4,6-di-*tert*-butyl-2-methylphenol, 2,6-di-*sec*-butyl-4-methylphenol, and 2,4,6-triisopropylphenol are insoluble in alkali. The latter are, however, soluble in the so-called Claisen solution (350 g potassium hydroxide in 250 g water made up to 1 L with methanol). In contrast to these partially sterically hindered alkylphenols, phenols with two bulky alkyl groups (e.g., *tert*-butyl, *tert*-pentyl) in the ortho and one alkyl group in the para position are also insoluble in the Claisen solution [24]. Examples of such sterically hindered (shielded) phenols are 2,6-di-*tert*-butyl-4-methylphenol, 2,6-di-*tert*-pentyl-4-methylphenol, and 2,4,6-tri-*tert*-butylphenol. The phenolates of these compounds can only be produced under special conditions [25], e.g., by treatment with solid potassium hydroxide and azeotropic removal of the water by an inert organic entrainer [26]. o-*tert*-Butylphenols without para alkyl groups behave differently; for example 2-*tert*-butylphenol and 6-*tert*-butyl-3-methylphenol are soluble in aqueous sodium hydroxide, and 2,6-di-*tert*-butylphenol is soluble to a certain extent in the Claisen solution. This is presumably because alkali salts of the corresponding tautomeric cyclohexadienones can be formed relatively easily. The insolubility of pentamethyl-, 4-*tert*-octyl, 4-nonyl,- or 4-dodecylphenol in cold aqueous alkalis is apparently due to the increase in the hydrophobic nature of the molecule because of the increasing number or length of the alkyl groups. These phenols are readily soluble in the Claisen solution. Alkylphenols which are insoluble in aqueous alkali but readily soluble in the Claisen solution are called cryptophenols.

The different solubility of the alkylphenols in alkalis can be used for their separation. As a result of the low acidity of the alkylphenols, they can even be liberated from their alkali phenolate solutions by carbon dioxide (p*K* 6.4).

Ether Formation. The hydroxyl group can be etherified, for example, with alkyl halides, halogenated carboxylic acids, or dialkyl sulfates in aqueous alkaline media. Bulky ortho alkyl groups hinder the reaction. In these cases the etherification can be forced by, for example, treating the anhydrous alkali phenolate with dimethyl sulfate in a solvent. If phase-transfer catalysts are used, it is possible to work in the presence of water. An example is the etherification of 2,4,6-tri-*tert*-butylphenol with dimethyl sulfate in aqueous sodium hydroxide – dichloromethane in 93 % yield in the presence of phase-transfer catalysts [27]. Alkylene oxides add to the hydroxyl group in the presence of basic catalysts to form alkylphenolmono- and polyglycol ethers (alkoxylation). The hydroxyl group can be etherified with alkenes in the presence of Friedel – Crafts catalysts under mild conditions.

Esterification. The hydroxyl group can generally be esterified successfully with acid anhydrides or acid chlorides. In the case of sterically hindered phenols, conditions have to be modified as with etherification [24]. With the exception of 2,6-di-*tert*-alkylphenols the hydroxyl groups of the alkylphenols react with isocyanates to form urethanes, which can be used for identification of the alkylphenols [28].

Substitution of the Hydroxyl Group. At 250 °C and in the presence of palladium – charcoal catalysts the OH group can be exchanged to yield the corresponding dialkylaniline [29]. This reaction occurs even with dialkylphenols such as 6-*tert*-butyl-2-methylphenol.

Hydrogenation. The hydrogenation of alkylphenols with hydrogen in the presence of Raney nickel or noble-metal catalysts leads to alkylcyclohexanols and/or alkylcyclohexanones. The latter are formed particularly in the case of sterically hindered alkylphenols [30], [31]. At high temperatures (250 – 350 °C) and in the presence of transition-metal – aluminum oxide catalysts, hydrogenolytic elimination of the alkyl groups and the hydroxyl group can also occur [32].

Oxidation. The coloration of alkylphenols in the presence of air indicates that they are sensitive to oxidation. Oxidation generally begins with the formation of phenoxy radicals. These radicals are relatively stable in the case of sterically hindered alkylphenols and are the reason why these phenols are particularly strong autoxidation inhibitors (⟶ Antioxidants). In the further course of the oxidation, many different compounds, some intensely colored, can be formed: hydroquinones, quinols, quinones, ketones, aldehydes, diphenoquinones, di-, tri-, and polyphenols, di-, tri-, and polyethers, and other C – C and/or C – O-linked products. Depending on the reaction conditions, oxidizing agent, catalyst, and nature and position of the alkyl group(s), certain products are formed preferentially [33-35]. Thus the formation of diphenoquinones is observed particularly in the case of 2,6-dialkylphenols with bulky alkyl groups. The 4-methyl group of 2,6-dialkyl-4-methylphenols can be often oxidized selectively to an aldehyde group (e.g., with pentyl nitrite, *tert*-butyl hydroperoxide – bromine, or oxygen) [33], [36], [37]. Strong oxidizing agents degrade the phenyl ring, e.g., the oxidation of alkylated phenols with potassium permanganate gives fatty acids.

Electrophilic Aromatic Substitution. Alkylphenols readily undergo electrophilic substitution. Substitution generally occurs in the positions ortho or para to the hydroxyl group, provided that they are not already occupied by other substituents. In particular when several or bulky alkyl groups are present, substitution (displacement) of alkyl groups by the electrophile can occur in addition to the normal substitution of hydrogen, or the reaction may stop at the stage of the cyclohexadienone, formed initially by addition of the electrophile. These types of anomalies are observed, for example, in nitrations [38], chlorinations [39], and in the reaction with trichloromethane – alkali (Reimer – Tiemann aldehyde synthesis) [40]. The nitration occurs even with dilute nitric acid and requires inert dilution agents and the careful maintenance of low temperatures to avoid undesired secondary reactions or a dangerous reaction process [38]. Nitrosation [41], chlorination [39], alkylation [42], and sulfonation, for example, take place with similar ease. The nitroso group preferably enters the ring para to the OH group. The nitrosophenols can also be present in the tautomeric quinone oxime form.

On heating alkylphenols, particularly in the presence of Friedel – Crafts catalysts, isomerization, transalkylation, and dealkylation can occur [43]. The tendency towards these reactions increases sharply in the order primary < secondary < tertiary alkyl groups. The isomerizations proceed until an equilibrium state is reached in which the thermodynamically more stable 3- and 3,5- (i.e., meta) isomers prevail. Groups in the para and ortho positions are cleaved particularly easily, those in the meta position less easily. Dealkylation can also occur during distillation of alkylphenols, if acids or potential acid-forming substances in the starting material are not completely removed or rendered ineffective (by addition of alkali). 1,1,3,3-Tetramethyl-5-indanol—which can be considered as ring-closed 3,4-di-*tert*-butylphenol and generally behaves as a typical phenol—however, shows remarkable stability towards dealkylation even in the presence of acids. The thermal stability of other indanols is also much higher than that of alkylphenols.

Heating alkali phenolates of alkylphenols with free ortho or para positions in the presence of carbon dioxide in polar, aprotic solvents such as dimethylformamide leads to hydroxyalkylbenzoic acids (Kolbe – Schmidt synthesis) [44]. Aldehyde groups can be very selectively introduced into the position para to the hydroxy group with zinc cyanide – hydrochloric acid. If this position is occupied, introduction into the ortho position occurs (Gattermann – Adams aldehyde synthesis) [45]. In the presence of alkali, formaldehyde reacts at room temperature with free ortho and para positions of alkylphenols to form hydroxymethyl-alkylphenols. Under acidic conditions or at higher temperatures these hydroxymethyl compounds condense with alkylphenols to form bis(hydroxyalkylphenyl)-methanes, and undergo autocondensation to yield high molecular mass alkylphenol – formaldehyde resins [46], [47]. The condensation of alkylphenols with formaldehyde in the presence of primary or secondary amines leads to Mannich bases [47]. The acidic condensation of alkylphenols with other aldehydes or ketones gives bis(hydroxyalkylphenyl)alkanes (see Section Production). Thiobisphenols are readily obtained with sulfur dichloride [48] and with disulfur dichloride, dithiobisphenols [49].

Alkenylphenols show a tendency towards dimerization and polymerization.

1.3. Occurrence, Formation, Isolation

Some alkylphenols such as 4-ethylphenol, 4-isopropylphenol (*p*-cumenol), 6-isopropyl-3--methylphenol (thymol), 5-isopropyl-2-methylphenol (carvacrol), 2,6-diisopropyl-3-methylphenol, 2,4-diisopropyl-5-methylphenol, 2,5-diisopropyl-4-methylphenol, and 4-allylphenol (chavicol) are components of natural essential oils, some of which have been used for centuries for the production of perfumes (⟶ Flavors and Fragrances). 2,3,4-Trimethylphenol, 5-ethyl-2-methylphenol, and 2,3-xylenol were detected in the defensive secretions of opilionides [50], and 2,6-di-*tert*-butyl-4-methylphenol is contained in Australian brown coal [51]. 3-(Pentadecen-8-yl)phenol, 3-(pentadecadien-8,11-yl)phenol, and 3-(pentadecatrien-8,11,14-yl)phenol have been identified as the main components of cardanol extracted from cashew nutshell oil on an industrial scale [52]. 3-Pentadecylphenol (hydrocardanol) is obtained from it by hydrogenation [53].

Alkylphenols are obtained in great number in the *purely thermal cracking* (low-temperature carbonization, coking, see ⟶ Coal Pyrolysis), in the *oxidizing thermal cracking* (gasification, ⟶ Gas Production), and the *hydrogenating thermal cracking* (⟶ Coal Liquefaction, ⟶ Coal Pyrolysis) of natural products such as bituminous coal, brown coal, peat, wood, lignin, and in the *coking thermal cracking* of crude oil fractions (⟶ Cresols and Xylenols – Formation and Isolation). Thus many different alkylphenols were detected in the various coal tars, some of them with several methyl, ethyl, *n*-propyl, isopropyl, *n*-butyl, isobutyl, *sec*-butyl, allyl, 1-cyclopentenyl, cyclohexyl, and/or indanoyl groups and various indanols and indenols. The unsaturated compounds are found in small quantities, mainly in low-temperature tars. Without taking the cresols and xylenols into account, about a hundred different monohydric phenols in total have been found in the various coal tars [54]. For the history of tar phenols see [55], [56].

The product distribution of the various cracking processes differs in the nature, but more in the ratio and particularly in the quantity in which the alkylphenols are produced, which depends on the starting material and the operating conditions. The mass ratio range of alkylphenols isolated from bituminous coal tars is given in Table 1.

Table 1. Alkylphenol content in bituminous coal tars

Alkylphenols	Low-temperature carbonization, wt %	Coking, wt %
Ethylphenols	42	47
Trimethylphenols	24	13
Ethylmethylphenols	13	15
Propylphenols	10	15
Methylpropylphenols	0.5	5
Tetramethylphenols	1	0.5
Diethylphenols		<0.5
Butylphenols		<0.5
Indanols	9	4

More details concerning product composition in bituminous coal coking are given in [57], and in various bituminous coal low-temperature carbonization processes in [58], [59].

Brown coal low-temperature tar contains a relatively high proportion of ethylphenols [59], [60]. Alkylphenols isolated from crude oil have a higher content of phenols with longer side chains, e.g., propyl- and butylphenols [61], [62]. In the hydrogenation of coal many indanols are formed [63], [64].

The strong influence of the cracking process on the total amount of monohydric phenols produced and on the proportion of alkylphenols among them is shown in Table 2.

Table 2. Phenol yields in the hydrogenation, low-temperature carbonization, and coking of bituminous coal, and in the cracking of gas oils

Reforming process	kg phenols per t H_2O-free raw material	
	Total *	Alkylphenols **
Hydrogenation	75	25
Low-temperature carbonization	15	3
Coking	0.7	0.04
Cracking	1	0.04

* Phenol + cresols + xylenols + alkylphenols (without phenol ethers etc.).
** Excluding cresols and xylenols.

In the distillative workup of the crude phenols obtained in the different cracking processes (⟶ Cresols and Xylenols – Isolation from Coal Tars), 2-ethylphenol (*bp* 204.3 °C) is distilled over with the *m*-/*p*-cresol fraction. The residue, which has a very complex composition, is usually worked up by batch distillation. Since the boiling points of the alkylphenols lie very close together and overlap to some extent with those of the xylenols and other compounds which may be present (e.g., phenol ethers), the production of certain alkylphenols in pure form is not possible by distillation. The products in the distillation range of ca. 205 – 285 °C are therefore separated only into particular fractions which depend on the application purposes and are characterized by their boiling ranges.

The distillate boiling between ca. 205 – 225 °C is generally called the xylenol fraction. If it originates from high-temperature bituminous coal tar, it can contain up to 30 % alkylphenols, predominantly 3- and 4-ethylphenol and methylethylphenols [57]. In xylenol fractions from East German brown coal low-temperature tars the xylenol content can be below 30 % and the 3-/4-ethylphenol content 40 % [65]. A 216 –218 °C xylenol fraction obtained from brown coal low-temperature tar phenols for the varnish industry contains predominantly 3- and 4-ethylphenol.

For the separation of 3- and 4-*ethylphenol* the same processes as for the separation of *m*- and *p*-cresol must be used (⟶ Cresols and Xylenols). Similar to *p*-cresol, 4-ethylphenol can be separated by esterification with oxalic acid [66]. The aforementioned 216 – 218 °C brown coal xylenol fraction, for example, is a suitable starting material for isolation of 3- and 4-ethylphenol.

2-*Ethylphenol* can be separated from the fraction boiling between 203 and 207 °C (in which it is enriched) as the quinaldine addition compound [67]. Other alkylphenols which can be enriched in narrow-boiling fractions and isolated pure by special methods, include 2,3,5-trimethylphenol (isopseudocumenol) [68], 2,3,6-trimethylphenol [69], 2,4,6-trimethylphenol (mesitol), 5-ethyl-3-methylphenol, 4-indanol, and 5-indanol [70].

Most of the alkylphenols with a boiling point > 230 °C are used as a mixture. The composition of an alkylphenol fraction boiling between 230 and 285 °C obtained from vertical retort bituminous coal tar is given in [71].

1.4. Production, General

1.4.1. *Alkylation of Phenols*

Alkylphenols are produced industrially mainly by catalytic alkylation of phenol, cresols, or xylenols with olefins which are readily accessible petrochemicals. Alcohols or halogenated hydrocarbons are only used as the alkylating agent if they are more readily available (e.g., cyclohexanol) or if the corresponding olefin does not exist (e.g., methanol, benzyl chloride). Other production processes for alkylphenols are less important than alkylation.

Ortho/Para Alkylation and Meta Isomerization in the Presence of Friedel – Crafts Catalysts [72-77]. The following Friedel – Crafts catalysts are mainly used in industry: sulfuric acid, phosphoric acid, *p*-toluenesulfonic acid, strongly acidic cation-exchange resins (e.g., Amberlite JR-112, Lewatit S 100), acid-activated silicates of the Montmorillonite type (bleaching clays), synthetic aluminum silicates of the crack catalyst type, boron trifluoride, aluminum chloride, iron(III) chloride, and zinc chloride.

The catalysts react with the alkylating agent to form an alkyl cation which is as branched (stable) as possible. The alkyl cation enters the nucleus preferentially in the positions ortho and para to the OH group according to the rules of electrophilic substitution. In addition, particularly under mild conditions, etherification of the OH group occurs. For the mechanism see [72-74].

The ratio of isomers formed initially is kinetically controlled and determined (1) by the position and inductive effect of the methyl (alkyl) group(s) already on the ring; (2) the reactivity of the alkyl cation; (3) the steric situation on the ring; and (4) the incoming alkyl group. Since the monoalkylation products are generally more reactive than the starting phenol, they

are further alkylated, provided that there is no steric hindrance. The ratio of mono- to di- and trialkylphenols is proportional to the ratio of phenol to alkylating agent.

During the further course of the reaction, rearrangements (isomerizations, transalkylations, disproportionations) occur and the product composition shifts in the direction of a thermodynamically more stable equilibrium state, in which phenols with meta alkyl groups finally prevail. During this process phenol ethers first rearrange to alkylphenols, the amount of di- and trialkylphenols is lowered, and the proportion of o-alkylphenols is shifted in favor of the p-alkylphenols, provided that the para position is free and is not sterically hindered.

Possible side reactions are (1) dealkylations; (2) di-and oligomerizations of the olefin used as alkylating agent or formed by dealkylation; (3) isomerization and cleavage in the alkyl groups (particularly in the case of larger and branched alkyl groups or olefins); (4) readdition of the olefins formed by cleavage, di- or oligomerization, (5) dehydrogenation of the alkyl to alkenyl groups and their reaction with olefins to form indanols; and (6) reactions of the catalyst with reaction components, e.g., the formation of phenolsulfonic acids and alkylsulfonates if sulfuric acid is used as catalyst. Ortho and para alkyl groups are much more prone to rearrangement and cleavage reaction than meta alkyl groups. The tendency towards rearrangement and cleavage reactions of ortho and para alkyl groups increases in the order of primary < secondary < tertiary alkyl groups. Methyl groups can only be made to migrate with great difficulty.

How fast a reaction mixture reaches thermodynamic equilibrium and the amount of side reactions that occur, depends on the nature of the phenol and that of the alkylating agent and on the severity of the reaction conditions, in particular on the activity (type) and quantity of the catalyst, on the temperature, the reaction time, and occasionally also on the water content of the reaction mixture. The reaction conditions must be carefully adjusted to achieve optimal product compositions.

High yields of a particular alkylphenol are often possible by making use of the rearrangement equilibria, so that the undesired ortho-/para-mono-, di-, and/or trialkylphenols formed as byproducts are separated from the desired product and recycled to the alkylation reaction. This is, however, not the case for 2-alkylphenols and 2,6-dialkylphenols: these compounds can only be obtained with the coproduction of considerable quantities of the corresponding phenols alkylated in the 4-position even under carefully controlled alkylation conditions and skillfully exploited rearrangement conditions. This is because, as previously indicated, ortho and para alkylations always occur simultaneously in the presence of Friedel – Crafts catalysts and the ortho isomer readily rearranges to the para isomer which is often thermodynamically more stable. This behavior has been intensively investigated in the *tert*-butylation of phenol with isobutene [78-83]. Good yields of 2-alkyl- or 2,6-dialkylphenols are possible if the para position is blocked by an alkyl group which will not migrate under the reaction conditions, e.g., a methyl group.

Ortho-Alkylation. In the presence of *aluminum phenolates*, phenols can be selectively alkylated with olefins in the ortho position. The catalyst is produced in the alkylation reactor before the addition of the olefin by heating the dry phenol with 1 – 2 wt % aluminum sand, powder, or turnings to 120 – 180 °C (with hydrogen formation). Depending on the olefin – phenol ratio, 2-alkyl- or 2,6-dialkyl-phenols are preferentially formed in the alkylation; at very high ratios 2,4,6-trialkylphenols are also formed. Currently 2,6-dialkylphenols, in particular, are produced using this process, which was developed independently by both Bayer [84] and Ethyl Corp. [85] in 1954. An overview of the reaction is given in the publications [86-89].

It is assumed that ortho selectivity is caused by the formation of a strongly acidic complex (**2**) from the aluminum phenolate (**1**) and the olefin, which directs the electrophilic attack of the olefin to the sterically more favorable position ortho to the OH group. The reaction ends with the reversal of the aluminum phenolate formation by proton exchange with excess phenol [90]:

Apart from the special ortho-directing effect and a somewhat lower activity of the aluminum phenolate, which can be compensated for by using higher temperatures, the process is very similar to the alkylation in the presence of Friedel – Crafts catalysts. Thus the reactivity of the olefins decreases in the order $R_2C = CH_2$ > R–CH = CH_2 ≈ R–CH = CH–R > CH_2= CH_2, and the alkyl group with maximum possible branching is formed. The ortho alkylation is also kinetically controlled and at the beginning of the reaction is accompanied by reversible ether formation which increases with increasing temperature. At too high a temperature and with longer reaction times dealkylation and the formation of para isomers also occur, especially if the alkylation has taken place more readily. Therefore, if a high yield of the ortho isomer is desired, it is necessary to work at the lowest possible temperature (which must nevertheless be sufficiently high for rapid ether cleavage) and at a high olefin concentration, and to stop the reaction at the optimum point in time. If lower olefins are used as alkylating agents, it is necessary to work under pressure in order to achieve a high olefin concentration [86], [87]. To avoid dealkylation and isomerization in the subsequent distillative workup, the aluminum phenolate catalyst is deactivated by, for example, addition of water or sodium hydroxide to the reaction mixture after the end of the reaction [91]. For ethyl- and *sec*-alkylphenols it may be possible to do without the catalyst removal, if distillation is carried out very carefully.

The ortho-selective effect of the aluminum phenolate is also seen in transalkylations. Thus under kinetically controlled conditions 2,4-di-*tert*-butylphenol and phenol react to form predominantly 2-*tert*-butylphenol [92]. In the case of dealkylation in the presence of aluminum phenolate, ortho-*tert*-alkyl groups are eliminated more rapidly than those in the para position [87], [93].

The aluminum phenolate catalyst can be obtained by treating phenol with aluminum or with reactive aluminum compounds such as aluminum alkoxides, aluminum trialkyls [94], dialkylaluminum chloride [95], or aluminum chloride [96]. To achieve smooth dissolution of aluminum, it can be activated by addition of mercury(II) chloride [86]. If toluenesulfonic acid is added during the aluminum phenolate, a hydrolysis-resistant mixed catalyst of similar ortho-selectivity is obtained [97]. Aluminum salts of the ortho phenolsulfonic acids are also suitable catalysts. Since they are not as readily soluble in the reaction mixture as the aluminum phenolates, they can be filtered off after the reaction has finished and reused [98]. Also compounds such as aluminum thiophenolate [99], aluminum diphenyldithiophosphate [100], polyphenoxy aluminum oxanes [101], and aluminum phenolate bonded to phenol – formaldehyde resin [102] have been proposed as ortho-alkylation catalysts.

In addition to aluminum phenolate which is used exclusively in industry, the phenolates of, e.g., magnesium, zinc, iron [84], [85], zirconium, hafnium, niobium, tantalum [103], gallium [104], and boron (aryl borates) [105], also have a pronounced ortho-selective effect. Titanium only shows this effect as the catecholate [106], or as the titanium phenolate – arylsulfonate mixed salt [107]. Zirconium, hafnium, niobium, and tantalum phenolates split off the 6-*tert*-butyl group from 3-alkyl-4,6-di-*tert*-butylphenols very selectively, whereas titanium phenolates are unsuitable for this partial dealkylation [108], [109].

γ-Aluminum oxide [110] and other modifications of aluminum oxide (apart from α-Al_2O_3) [111] also direct the alkyl group very selectively into the ortho position, if olefins are reacted with phenols in the liquid phase at 200 – 350 °C and 2 – 20 MPa. In industry these types of aluminum oxide are used particularly for the production of ortho-monoalkylphenols, because they lead to a clearly higher ortho-mono/ortho-dialkylphenol ratio than aluminum phenolate if the same olefin/phenol ratio is used (e.g., 1 : 1). Moreover, they have the advantage over aluminum phenolate — unless it is fixed in a resin [102] — that they can be readily separated after the reaction by, for example, filtration, and reused or used in a fixed-bed form in continuous processes. For the effect of the double bond position in the olefin on the yield of ortho-alkylphenols on γ-Al_2O_3, see [112].

High selectivities were observed, for example, with oxides of the elements of groups 15 and 17 of the Periodic Table [113], and with high-purity silicon dioxide [114]. The activity of the metal compounds can be increased by applying them to a carrier such as Al_2O_3 or silicates [113], [115].

Relatively high ortho selectivities are also observed if olefins are heated with phenols *in the absence of catalysts* in the liquid phase to 300 – 400 °C under pressure [116]. This so-called *thermal alkylation* has been known for a long time [117], but has so far remained unimportant industrially. The conversions are moderate and the yields based on olefin are poor. Long-chain linear α-olefins become bonded to the phenol preferentially at their C-2 atoms to give ortho-monoalkylphenols. Unlike the situation with Friedel – Crafts catalysis, bonding at C-1 has been observed, but hardly any at the middle C-atoms of the olefin chain, and no para substitution [118]. It is assumed that the thermal ortho-alkylation takes place via a 6-membered, cyclic transition state, into which the phenolic OH group is incorporated [116], [118].

Alkylation Rules. The position that an alkyl group can occupy in the phenyl ring depends on the size of the entering group and on the alkyl group already present. For cresols and xylenols the following rules are generally valid:

1. *Secondary alkyl groups* such as isopropyl, *sec*-butyl, cyclopentyl, and cyclohexyl can enter the ring between the hydroxyl and a meta-methyl group, but not between two methyl groups meta to each other. For example, propylation of 3,5-xylenol can yield 2,6-diisopropyl-3,5-dimethylphenol, but not 4-isopropyl-3,5-dimethylphenol.
2. *Tertiary alkyl groups* such as *tert*-butyl, *tert*-pentyl, and *tert*-octyl are unable to enter the ring between the hydroxyl and a methyl group meta to it. This means that, for example, 3,5-xylenol cannot be *tert*-butylated.
3. Unlike *sec*-alkyl groups, *tert*-alkyl groups do not migrate to positions next to a para methyl group. 4-Methyl-3-*tert*-butylphenol therefore cannot be synthesized by isomerization of 4-methyl-2-*tert*-butylphenol in the presence of alkylation catalysts.

For the polyalkylation of phenols with various alkyl groups, the most sensitive (tertiary) group must be introduced last. For example, for the production of 4-*tert*-butyl-2-cyclopentylphenol the *sec*-cyclopentyl group is first introduced (with aluminum phenolate) and then the *tert*-butyl group (with a Friedel – Crafts catalyst).

General Information on Alkylation of Phenol with Olefins. Alkylation is carried out predominantly in the liquid phase without a solvent. In the presence of Friedel – Crafts

catalysts, normal or slightly increased pressure and a temperature range of ca. 30 – 150 °C are generally used. Higher pressures and/or temperatures can be necessary for the meta isomerization or for alkylations in the presence of ortho-selective catalysts (see below). The plant is generally inerted with nitrogen before alkylation.

To be able to adapt to the different starting materials and changing market demands with regard to the nature and quality of the alkylphenol, most alkylphenols are produced batchwise in multipurpose plants. For compounds produced in large quantities such as thymol, 2-*sec*-butylphenol, 4-*tert*-butylphenol, 2,6-di-*tert*-butylphenol, 2,6-di-*tert*-butyl-4-methylphenol, octylphenol, and nonylphenol there is a trend towards specialized continuous or semibatch plants.

The choice of catalyst depends, e.g., on the reactivity of the phenol and of the alkylating agent, the desired product composition (isomer distribution, byproducts), the cost, or the available possibilities with regard to the corrosion resistance of the plant, catalyst removal from the reaction mixture, disposal of the catalyst and/or its decomposition products, workup of the product mixture, the quantity of the product, and its value.

Protonic acids such as H_2SO_4 are readily available, cheap, and so active that small quantities (1 – 2 wt %) are sufficient to obtain high space – time yields at relatively low temperatures. However, they are corrosive and must be removed or rendered ineffective in order to obtain a stable, distillable product. This requires careful scrubbing of the alkylphenol with alkali hydroxides and water, thus producing wastewater which must subsequently be treated. A similar situation exists if metal halides and metal phenolates are used.

Solid inorganic catalysts (acid-activated bleaching clays, oxides of aluminum and silicon etc.) must be added in finely divided form at higher temperatures and in larger quantities (2 –5 wt %, for isomerizations even up to 10 wt %) to compensate for their lower activity. They are, however, less corrosive than protonic acids and have the advantage in process technology that they can be separated simply by filtration. However, filtration must be carried out carefully because catalyst particles which have passed through the filter can lead to dealkylation at high distillation temperatures. The disposal of the depleted catalyst loaded with phenol can be problematic.

Cation exchangers [76] are reusable (long service life), highly selective for monoalkylations, noncorrosive, can be readily separated from the alkylated phenol, and do not produce any wastewater. These advantages are best realized if they are used in continuous alkylations as bead polymers arranged in a fixed bed. When used in suspended form they can lead to formation of abrasion particles, which must be completely separated or neutralized by addition of alkali to the alkylated phenol, so that dealkylation does not occur in the subsequent distillations. The upper operating temperature of the cation exchanger is ca. 140 °C; at this temperature, however, clear loss of activity must be taken into account in continuous operation. Powder cation exchangers have a higher activity and are more effective for dialkylation than the bead exchangers [74].

After separation of the catalyst the reaction mixture is worked up by fractional distillation in vacuum. Unreacted starting material, undesired ortho and para isomers, and high-boilers are recycled to the reaction as far as possible. Isolation of a particular isomer is often laborious and frequently unnecessary: for many industrial applications alkylphenols are only separated from starting material and high-boilers by distillation, and are used as a mixture of isomers. Occasionally, the separation of high-boiling substances is not required, and stripping of the alkylation product is sufficient as the workup step. In special cases even the catalyst separation and distillation are not performed and the crude alkylation product is led directly into the subsequent reaction [119].

1.4.2. *Other General Processes*

Alkylphenols which are not readily accessible or totally inaccessible by alkylation, e.g., those with long primary alkyl groups (≥ 3), can be obtained as follows:

Reduction of acylphenols (phenolketones) which are obtained by Friedel – Crafts acylation of phenols or by the Fries rearrangement of phenol esters [120], [121]:

Alkali fusion of alkylbenzenesulfonates, which are obtained by sulfonation of alkylbenzenes [122] (⟶ Cresols and Xylenols – Alkali Fusion of Toluenesulfonates):

Cleavage of bis(4-hydroxyphenyl)alkanes, either alkali-catalyzed [123], [124] with hydrogen in the presence of a hydrogenation catalyst [125], [126], or with a hydrogen donor such as cyclohexanol:

Claisen rearrangement of allyl aryl ethers into allylphenols [127], if necessary with subsequent rearrangement into vinylphenols [128] or hydrogenation to alkylphenols:

The Claisen rearrangement is particularly suitable for the introduction of alkyl groups into the position ortho to an OH group, the other methods are preferentially used for the production of para-alkylphenols.

Other possibilities can be found in *Houben – Weyl* (see general references). Alternatives to phenol alkylation are also discussed in the following section.

1.5. Industrially Important Alkylphenols

1.5.1. *Polymethylphenols*

2,3,6-Trimethylphenol, 2,4,6-trimethylphenol, and other polymethylphenols are formed in small quantities as byproducts in the production of cresol and particularly xylenol by methylation of phenol (⟶ Cresols and Xylenols – Methylation of Phenol, ⟶ Cresols and Xylenols).

2,3,6-Trimethylphenol [2416-94-6] (physical properties see Table 3) is produced selectively by gas phase methylation of *m*-cresol with methanol at 300 – 460 °C under normal pressure on ortho-selective metal oxide catalysts, as used for the selective methylation of phenol (⟶ Cresols and Xylenols – Methylation of Phenol). The reaction occurs in multitube reactors with a fixed catalyst. The reaction temperature to be maintained depends on the catalyst used in each case. Iron oxide catalysts modified with oxides of other metals (e.g., Zn [129], Cr and Sn[130], or Mg and Si [131]) are particularly suitable for the process. At temperatures of ca. 350 °C and a liquid hourly space velocity (LHSV) of ca. 1 h_{-1}, an initial mixture of *m*-cresol, methanol, and steam in a molar ratio of 1 : 6 : 1 gives 2,3,6-trimethylphenol in yields of 90 – 95 % (relative to *m*-cresol) at virtually complete *m*-cresol conversion. Small quantities of 2,5-xylenol and 2,4,6-trimethylphenol are the main byproducts. About half the methanol decomposes to H_2, CH_4, and CO_2. The reaction mixture is worked up by distillation. For the workup by recrystallization from aliphatic hydrocarbons, see [132]. The commercial product is ≥ 99 % pure.

Table 3. Physical properties of some polymethylphenols and ethylphenols

Name (common name)	Formula	CAS registry number	M_r	*mp*, °C	*bp* at 101.3 kPa, °C	*bp* at 2.66 kPa, °C	ΔH_V at *bp* 101.3 kPa, kJ/mol	d_4, g/cm^3 (°C)	n_d (°C)	p*K* at 20 °C

2,3,6-Trimethylphenol can also be obtained by methylation of 2,6-xylenol on γ-aluminum oxide, in particular if the reaction is carried out in a trickle bed [133]. Under optimum conditions (a molar ratio 2,6-xylenol – methanol of 2 : 1, 355 °C, 3.2 MPa, LHSV 4 h^{-1}, multitube reactor), however, a selectivity of only 50 % is achieved at 32 % conversion [134]. From the xylenol – trimethylphenol fractions thus obtained the 2,3,6-trimethylphenol must be isolated in pure form [126] by relatively sophisticated procedures, i.e., by alkaline countercurrent extraction [135] or, after spreading out the boiling points by *tert*-butylation of the mixture, by fractional distillation, debutylation, and a second fractionation [136].

Another industrial route to 2,3,6-trimethylphenol developed by BASF involves the condensation of diethyl ketone in the presence of base (NaOH) with methyl vinyl ketone [137] or crotonaldehyde [138] to give 2,3,6- and 2,5,6-trimethyl-2-cyclohexen-1-ones, respectively. These compounds are subsequently dehydrogenated in the gas phase at 250 – 300 °C on noble metal carrier catalysts [139]:

The condensation to give the trimethylcyclohexenones takes place in excess boiling diethyl ketone in yields of ca. 80 % [137], [138]. The selectivity of the dehydrogenation is 97 % on palladium – spinel catalysts, if the trimethylcyclohexanone that is formed as a byproduct in up to 10 – 15 % yield by hydrogenation is recycled into the dehydrogenation [139]. The dehydrogenation can also be performed at 220 – 225 °C on 1 % palladium – charcoal catalysts [140].

2,4,6-Trimethylphenol [527-60-6] (physical properties see Table 3) is the main product (> 80 %) of the gas phase alkylation of phenol with excess methanol (molar ratio 1 : 5) at 450 °C on magnesium oxide catalysts, which are doped with alkali or other metal oxides (e.g., V_2O_5, SrO). 2,6-Xylenol and 2,3,4,6-tetramethylphenol are the main byproducts [141], [142].

2,3,5-Trimethylphenol [697-82-5] and *2,3,5,6-tetramethylphenol* [527-35-5] (physical properties of both compounds are given in Table 3) are obtained by methylation of 3,5-xylenol in the presence of ortho-selective catalysts. A mixture of 3,5-xylenol – methanol vapors (molar ratio 1 : 5) is continuously reacted in a tubular reactor on a mixed MgO – UO_3 catalyst at 400 °C and an LHSV of 1 h^{-1}. The conversion of 3,5-xylenol is 75 %; a 2,3,5-trimethylphenol selectivity of ca. 75 % and a 2,3,5,6-tetramethylphenol selectivity of ca. 25 % are obtained [143].

In the same way *p*-cresol and 2,4-xylenol can be converted into *2,4,6-trimethylphenol*; 2,3- and 2,5-xylenol into *2,3,6-trimethylphenol*; and 3,4-xylenol into a mixture of *2,3,4-trimethylphenol*, *2,4,5-trimethylphenol* [496-78-6] (physical properties see Table 3) and *2,3,4,6-tetramethylphenol* [3238-38-8] (physical properties see Table 3) on ortho-selective

methylation catalysts.

2,4,6-Trimethylphenol can be isomerized in the presence of $AlCl_3$ – HCl at 85 °C to a mixture of 62 % 2,3,6-, 26 % 2,3,5-, and 12 % 2,4,6-trimethylphenols [144]. Under more stringent conditions all trimethylphenols rearrange in the presence of $AlCl_3$ – HCl to form the thermodynamically stable 2,3,5-trimethylphenol in good yields [145].

Producers. Producers of 2,3,6-trimethylphenol are, for example, Synthetic Chemicals in the United Kingdom, BASF and Lowi in Germany, and Honshu Chem. Ind. in Japan. 2,4,6-Trimethylphenol is produced by Lowi in Germany, General Electric in the United States, and Konan Chemicals, Mitsubishi Gas, and Nippon Kagaku in Japan. 2,3,5-Trimethylphenol is produced by Shell Chemicals in the United Kingdom.

Uses. *2,3,6-Trimethylphenol* is an important starting material for vitamin E synthesis (⟶ Vitamins); it also serves as a comonomer for the modification of polyphenyleneoxide resins (PPO). *2,3,5-Trimethylphenol* and *2,4,6-trimethylphenol* [142] are also starting materials for vitamin E. A mixture of the *N*-methylcarbamates of 2,3,5-trimethylphenol and 3,4,5-trimethylphenol is used as an insecticide.

The *tar alkylphenols* with a boiling point > 230 °C (to which the trimethylphenols and methylethylphenols belong) show bactericidal, fungicidal, and insecticidal action. Therefore these alkylphenols are contained in formulations of impregnating oils used for wood protection.

1.5.2. *Ethylphenols*

2-Ethylphenol [90-00-6] and *2,6-diethylphenol* [1006-59-3] (for physical properties of both compounds see Table 3) are produced industrially by ortho-alkylation of phenol with ethylene in high pressure autoclaves at 320 – 340 °C and 20 MPa in the presence of 1 – 2 % aluminum phenolate. If a molar ratio of phenol – ethylene of ca. 1 : 2 is used, the yield (related to converted phenol) is ca. 32 % 2-ethylphenol and ca. 39 % 2,6-diethylphenol after 6 h reaction time. About 17 % 6-*sec*-butyl-2-ethylphenol is formed as a byproduct [86].

Cresols and xylenols with free ortho positions can be ethylated similarly. The ethylation of 3,5-xylenol leads very smoothly to *2-ethyl-3,5-dimethylphenol* and *2,6-diethyl-3,5-dimethylphenol* [86].

Phenol can also be ethylated with ethanol , [146-149]. The conditions are similar to those for the methylation of phenol with methanol. A yield of 60 % 2-ethylphenol and 22 % 2,6-diethylphenol is achieved using an Fe_2O_3 catalyst doped with silicon and magnesium oxides in the gas phase at 360 °C (molar ratio phenol – ethanol – H_2O 1 : 6 : 1, LHSV of 0.6 h^{-1}) [131]. 2-Ethyl- and 2,6-diethylphenol are also formed preferentially on Al_2O_3 in the gas phase at ca. 300 °C [147]. With increasing temperature and residence time the ortho-selectivity decreases and the yield of 3- and 4-ethylphenol increases [148]. At 400 – 450 C° mixtures of isomers with a relatively high proportion of meta product can be obtained, in particular after increasing the isomerization and transalkylation activity of the catalyst by combination of the catalyst with other compounds [149]. If phenol is reacted with ethylene instead of ethanol, ca. 77 % conversion of phenol is achieved. Phenol and ethylene react, for example, in the gas phase at 420 °C on a phosphoric acid – SiO_2 catalyst to form an ethylphenol mixture, of which ca. 44 % is 3-ethylphenol [150]. The processes give product mixtures from which the pure meta or para isomers can only be isolated at relatively high cost. An especially high 4-ethylphenol selectivity (ca. 96 %) is possible according to [151] with ethylene – phenol – H_2O vapor mixtures (molar ratio 1 : 0.86 : 1.3) at 400 °C and low phenol conversions (ca. 7 %) on H-ZSM-5-zeolite modified with tetramethoxysilane. As far as is known these processes have not been exploited industrially.

4-Ethylphenol [123-07-9] (for physical properties see Table 3) is produced industrially by sulfonation of ethylbenzene under mild (kinetically controlled) conditions [152] and subsequent alkali fusion of the 4-ethylbenzenesulfonic acid obtained [153], [154]. The purity of the commercial product is 98 %.

3-Ethylphenol [620-17-7] (for physical properties see Table 3) is also produced by sulfonation of ethylbenzene and subsequent alkali melt of the 3-ethylbenzenesulfonic acid obtained. By sulfonation under severe (thermodynamically controlled) conditions (200 °C) the 4-ethylbenzenesulfonic acid formed initially isomerizes to form a mixture of 2-, 3-, and 4-ethylbenzenesulfonic acids in a ratio of ca. 2 : 58 : 40. The 2- and 4-ethylbenzenesulfonic acids are selectively hydrolyzed back to ethylbenzene and H_2SO_4 by blowing steam through the mixture at 150 – 170 °C. 3-Ethylphenol is then obtained by alkali melt of the remaining 3-ethylbenzenesulfonic acid at 330 – 340 °C in up to 98 % purity [155-157].

Producers. Producers of 2-ethylphenol are, for example, EMS-Dottikon in Switzerland and Coalite in the United Kingdom. 4-Ethylphenol is produced, e.g., by Synthetic Chemicals and Coalite in the United Kingdom and Maruzen Oil Co. and Konan Chemicals in Japan. Producers of 3-ethylphenol are, e.g., Coalite and Synthetic Chemicals in the United Kingdom and Taoka Chem. Co. in Japan.

Uses. 3-Ethylphenol and 4-ethylphenol are contained in the xylenol fraction boiling between ca. 205 and 225 °C obtained from tar phenols, which is used, for example, for the production of phenolic resins. A xylenol fraction boiling between 216 and 218 °C containing predominantly 3- and 4-ethylphenol is obtained from brown coal low-temperature tar and used in the varnish industry.

Pure 2-ethylphenol and 3-ethylphenol are starting materials for photochemicals. Pure 4-ethylphenol is the starting material for the production of 4-vinylphenol and of various antioxidants [e.g., 2,6-di-*tert*-butyl-4-ethylphenol and 2,2′-methylenebis(6-*tert*-butyl-4-ethylphenol)], which are used in rubber and polymers. 4-Ethylphenol is an intermediate for pharmaceuticals and dyes.

1.5.3. *Isopropylphenols*

Properties. Some physical properties of isopropylphenols mentioned in this article are listed in Table 4.

Table 4. Physical properties of isopropylphenols

Name (common name)	CAS registry no.	*mp*, °C	*bp*, °C
2-Isopropylphenol	[88-69-7]	16.8	215.5
3-Isopropylphenol	[618-45-1]	25.7	223.5
4-Isopropylphenol	[99-89-8]	63	223

2,4,6-Triisopropylphenol	[2934-07-8]	28.7	255
5-Isopropyl-2-methyl-phenol (carvacrol)	[499-75-2]	2.5	237.4
6-Isopropyl-2-methyl-phenol	[3228-04-4]	–16.5	225
2-Isopropyl-3-methyl-phenol	[3228-01-1]	70 – 70.5	229
4-Isopropyl-3-methyl-phenol	[3228-02-2]	114	245
5-Isopropyl-3-methyl-phenol (isothymol)	[3228-03-3]	51	241
6-Isopropyl-3-methyl-phenol (thymol)	[89-83-8]	51.5	232.4
2-Isopropyl-4-methyl-phenol	[4427-56-9]	34	234

Production. Isopropylphenols are formed by reaction of phenol or alkylphenols with propene or isopropanol in the presence of acid catalysts of the Lewis or Brønsted type or of aluminum phenolate. An extensive study of the alkylation of phenol, both with propanol and isopropanol in the presence of alumina has been published [158].

Industrially, *2-isopropylphenol* is produced from phenol and propene using ϒ-Al_2O_3 as the catalyst. The alkylation is carried out continuously in a steel tube filled with ϒ-Al_2O_3 pressed into tablets, with graphite as a tabletting aid. The reaction temperature is 250 – 300 °C and the pressure is about 10 MPa, to keep both the phenol and the propene safely in the liquid phase. If a phenol : propene molar ratio of 1.3:1 is used, 2-isopropylphenol is obtained with a selectivity of about 85 % at complete propene conversion [159].

2,6-Diisopropylphenol is formed as a byproduct (10 – 12 %) in this process along with smaller amounts of *4-isopropylphenol* (1 – 2 %) and *isopropyl phenyl ether* [2741-16-4] (*bp* 176.8 °C). The proportion of ether formed increases considerably at temperatures below 250 °C. Isopropyl phenyl ether, once formed, remains unchanged over the alumina catalyst even at 250 – 300 °C. Isopropyl phenyl ether can be transformed mainly to 2-isopropylphenol by treatment at 85 °C with BF_3 [160] or with strongly acidic ion-exchange resins.

Monoisopropylphenol mixtures enriched in the 4-isomer can be synthesized from phenol and propene or isopropanol in the presence of zeolite catalysts [161], [162]. When a 1 : 1 molar mixture of phenol and isopropanol is passed over a ZSM-5-catalyst at 250 °C and LHSV = 1 h^{-1}, a phenol conversion of 20 % and a selectivity for 4-isopropylphenol of 63 % is achieved [161]. 1 : 1 Mixtures of 2- and 4-isopropylphenols are obtained by transalkylation of phenols with cumene in a HF – BF_3 medium at 30 °C [163].

Isomerization and transalkylation occur if (mixtures of) 2- and/or 4-isopropylphenol(s) are heated to 110 °C for 6 h in BF_3-containing hydrogen fluoride. The main reaction product is

3-isopropylphenol which is obtained in 61 % yield [164].

3- and 4-Isopropylphenol are minor byproducts of commercialized resorcinol and hydroquinone syntheses (⟶ Resorcinol ; ⟶ Hydroquinone) that use 1,3- and 1,4-diisopropylbenzene, respectively as starting materials. Production of 3- or 4-isopropylphenol via this autoxidation route is, however, not economical.

2,6-Diisopropylphenol is produced from phenol and propene (molar ratio 1 : 2.1) with homogeneously dissolved aluminum phenolate as catalyst, which is formed by dissolution of aluminum granules (1 wt %) in the educt phenol. The alkylation is carried out in an autoclave or pressure tube and takes place at 220 °C within 3 h. The workup procedure involves: (1) treatment of the reaction product with aqueous mineral acid to destroy the phenolate catalyst; (2) phase separation, (3) neutralization of the acid entrained in the organic phase with a base; and (4) a water wash. The product is subsequently distilled to yield 77 % 2,6-diisopropylphenol and 10 % 2-isopropylphenol [165], [166]. The wastewater is contaminated with phenolic compounds; therefore the procedure needs to be improved because of ecological considerations.

2,4,6-Triisopropylphenol is obtained in 70 % yield by reacting 1 mol phenol with 4 mol propene at 250 °C under pressure in the presence of fluorided alumina [167]. Diisopropylphenols are formed as byproducts. Mixtures of mono- di-, and triisopropylphenols can be produced from phenol and propene with aluminum chloride (at 50 – 150 °C) [168], [169] or with activated clays (at 100 – 150 °C) as catalysts [170]. These mixtures find various applications in the plastics industry. If desired, the proportion of 3- or 3,5-isomers can be increased by (1) raising the temperature (up to 200 °C), (2) increasing the amount of catalyst (up to 20 %) and/or (3) increasing the reaction time (> 20 h) [171]. The reaction mixtures are fractionated and fractions with desired composition are recycled to the alkylation reactor. If $AlCl_3$ is used as the catalyst, the mixture can be reacted with phosphorus oxychloride to form phosphoric acid tris(isopropyl phenyl ester) [168], [172]. Phenol alkylation and subsequent esterification of the alkylphenol can thus be carried out in one reaction vessel without intermediate separation of the catalyst and fractionation of the reaction mixture.

Several isopropylation products of the methylphenols (cresols) are used industrially. The most important is the *m*-cresol-derived *6-isopropyl-3-methylphenol* (*thymol*), a precursor of l-menthol (⟶ Flavors and Fragrances). *m*-Cresol with a purity ≥ 98.5 % must be used as the starting material for thymol production, because 2-isopropyl-4-methylphenol, derived from *p*-cresol (the main contaminant of commercial *m*-cresol), cannot be easily separated from thymol.

In the industrial process employed by Bayer [173], *m*-cresol and propene, both in the liquid state, are pumped through a pressure tube filled with activated alumina. The process is performed at a molar ratio of *m*-cresol – propene of 1 : 0.7, at 350 – 365 °C, ca. 5 MPa, and an LHSV of 0.25 h^{-1}. The reaction product consists of ca. 25 % *m*-cresol, 60 % thymol, and 15 % other products. Thymol of ≥ 99.5 % purity is obtained by rectification of the crude product. Undesired alkylates of *m*-cresol (2-, 4-, and 5-isopropyl-*m*-cresol; 2,6- and 4,6-diisopropyl-*m*-cresol) are recycled to the reaction zone to achieve a high overall yield of the desired thymol.

The influence of the reaction conditions on the formation of thymol from *m*-cresol and propene in the liquid phase in the presence of γ-Al_2O_3 has been described [175]. Impregnation with metal sulfates, e.g., $FeSO_4$, increases the activity of γ-Al_2O_3 [176], [177]. Aluminum phenolate [178] and aqueous zinc halide – hydrogen halide solution [179] have also been used as catalysts. With these systems selectivities for thymol formation are about 75 –80 %.

In 1988, a gas phase process for thymol manufacture was developed using medium-pore sized zeolites (e.g., erionite, mordenite, or ZSM-23) as heterogeneous catalyst; 80 – 100 % of the exchangeable cations in the zeolite are present as protons. Reaction temperatures are lower (230 –270 °C) than in the older liquid-phase process and the reaction pressure is normal or slightly elevated [174].

5-Isopropyl-3-methylphenol (isothymol) can be produced by employing catalysts that possess high isomerization and transalkylation activities. Examples include finely ground synthetic silica –alumina [180] and synthetic zeolites with faujasite structure, especially the wide-pored Y-type [181]. Acid-activated clays are less suitable as catalysts because they can lead to corrosion at the relatively high temperatures that are required for isomerization. Usually, the isothymol synthesis is conducted in two steps. First, 1 mol *m*-cresol is reacted with < 1 mol propene at 100 –200 °C in the presence of one of the aforementioned catalysts (10 wt % silica – alumina or 5 wt % zeolite Y). The alkylate is then kept in an autoclave at 300 °C until the thermodynamic equilibrium is established (ca. 5 – 10 h). The equilibrated mixture contains 5-, 6- and 4-isopropyl-*m*-cresols in a 75 : 20 : 5 ratio together with unreacted *m*-cresol and higher alkylates. The higher the excess of *m*-cresol used initially, the lower is the proportion of higher alkylates obtained. Using an efficient fractionating column, isothymol is distilled from the reaction mixture after removal of the catalyst by filtration. Undesired isomers of isothymol and higher alkylates can be recycled to the isomerization – transalkylation step for optimization of the yield. Isothymol can also be separated from its isomers, by alkylation (with isobutene) [182] or sulfonation (with sulfuric acid) of the isomeric mixture [183]. In contrast to its isomers, isothymol does not react with both compounds and thus can be separated from its alkylated/sulfonated isomers by a less efficient separation column. Isopropylation of *o*- and *p*-cresol yields rather complex product mixtures, depending on reaction conditions.

o-Cresol is isopropylated under kinetic control and with aluminum phenolate as catalyst to form *6-isopropyl-2-methylphenol* in good yield [178], which in turn can easily be isomerized to *4-isopropyl-2-methylphenol* by treatment with catalytic amounts of sulfuric acid at 60 °C [184]. Under thermodynamic control, at 300 °C, and with an activated clay as catalyst, the main product is *5-isopropyl-2-methylphenol (carvacrol)* [185].

p-Cresol reacts with propene in the presence of aluminum phenolate [178] or BF_3 – phosphoric acid [186] as catalysts to give 2-isopropyl-4-methylphenol and 2,6-diisopropyl-4-methylphenol under kinetic control. Conditions which establish the thermodynamic equilibrium lead to the additional formation of *3-isopropyl-4-methylphenol* and *2,5-* and *3,5-diisopropyl-4-methylphenols*. Product distributions resulting from the reaction of cresols with isopropanol in the presence of $AlCl_3$ and phosphoric acid have been studied [187-189].

If *xylenols* are to be isopropylated, the substitution rules given on page Alkylation Rules. can be applied to predict the composition of the resulting product mixtures.

Uses. Isopropylphenols have found relatively few commercial applications. As nontoxic substitutes the phosphate esters of isopropylphenol mixtures are used for cresylphosphates as secondary plasticizers and flame retardants in vinyl polymers, mainly poly(vinyl chloride) [167], [168]. 2-Isopropylphenol is an efficient antiskinning aid in air-drying coatings. 6-Isopropyl-3-methylphenol (thymol) is the starting material for an industrial l-menthol synthesis [190] (⟶ Flavors and Fragrances). Thymol and carvacrol (5-isopropyl-2-methylphenol) are used as antiseptics. The *N*-methylcarbamate derived from 5-isopropyl-3-methylphenol is a very efficient insecticide [181]. 2,4,6-Triisopropylphenol can be used as an antioxidant in motor fuels and lubricants [167]; its reaction products with alkylene oxides are reported to be useful nonionic surfactants with good surface activity and low foaming properties [191].

1.5.4. *sec-Butylphenols*

2-sec-Butylphenol [89-72-5], *mp* 12 °C, *bp* 226 – 228 °C, is obtained with high selectivity by reaction of phenol with *n*-butenes at 250 – 300 °C using γ-Al_2O_3 as catalyst and at a pressure of 3.5 – 8.0 MPa which keeps both reactants in the liquid phase. If the reaction is performed batchwise, the catalyst is finely ground and kept in suspension by stirring. In a continuous operation the catalyst is pressed into tablets with 10 – 20 % graphite as a tabletting aid, and positioned in a pressure tube. Typically, phenol and *n*-butene(s) in a 4 : 1 molar ratio are pumped over the catalyst at 250 °C, 3.5 MPa, with a residence time of 1 h. Conversions are 22 % (phenol) and 90 – 96 % (*n*-butenes); the selectivities for 2-*sec*-butylphenol and 4-*sec*-butylphenol [99-71-8] (*mp* 56 –61 °C, *bp* 135 – 136 °C at 3.33 kPa) are 95 % and 2.5 %, respectively. *sec*-Butyl phenyl ether [10574-17-1] (*bp* 101 – 103 °C at 5.8 kPa) is formed as a byproduct [192]. A gas-phase alkylation employing a multitubular reactor has been described [193].

Aluminum phenolate (prepared in situ by dissolving about 3 wt % of aluminum granules or chips in the educt phenol) can also be used as the alkylating catalyst. Alkylation takes place with *n*-butene(s) at temperatures of 150 – 180 °C and by increasing pressure up to ca. 5 MPa. Depending on the amount of butene(s) introduced, either 2-*sec*-butylphenol or 2,6-di-*sec*-butylphenol [5510-99-6] (*mp* 42 °C, *bp* 225 – 260 °C) is obtained as the principal product. The usual workup (treatment with aqueous mineral acid to destroy the catalyst) can be circumvented by flash distillation of the crude reaction product at temperatures < 225 °C (vacuum). Under these conditions dealkylation is prevented and the catalyst-containing distillation residue can be recycled back to the alkylation step [194]. Alternatively, the distillation residue can be subjected to a transalkylation reaction after addition of phenol and heating to 250 – 350 °C [195].

Producers. 2-*sec*-Butylphenol is commercially produced by Hüls, Ethyl, Pearson, Shell, and Schweizerische Teerindustrie AG (STIAG). On request 2,6-di-*sec*-butylphenol will also be provided. Product purities are about 98 %. The main use of 2-*sec*-butylphenol is in the synthesis of insecticides, acaricides, and herbicides.

1.5.5. *tert-Butylphenols*

Properties. Boiling and melting points of selected *tert*-butylated phenols as well as a qualitative note on their solubility in alkali are listed in Table 5. Solubility in 2.5 N NaOH can be useful for separating substances with similar boiling points.

Table 5. Physical properties of *tert*-butylphenols

Name	CAS registry no.	*mp*, °C	*bp*, °C 101.3 kPa	*bp*, °C (kPa)	Solubility in 2.5 N NaOH *
2-*tert*-Butylphenol	[88-18-6]	–7	224	99 (1.33)	s
3-*tert*-Butylphenol	[585-34-2]	43	240	129.5 (2.66)	s

* s = soluble; i = insoluble.

Production. *2-tert-Butylphenol* is obtained as the main alkylation product if phenol is reacted with isobutene in the presence of sulfonated polystyrene – polydivinylbenzene ion-exchange resins. The acidity of the ion-exchange resins is depressed to an exchange capacity of about 2.5 meq/g (dry weight) by having been used for related reactions, e.g., for the production of higher alkylphenols [196]. For a definition of exchange capacity, see ⟶ Ion Exchangers – Exchange Capacity. A preconditioned catalyst of this kind that is placed in a tower reactor on a supporting sieve, permits production of 2-*tert*-butylphenol on an industrial scale. Reaction of phenol and isobutene in a 1 : 0.42 molar ratio at 95 °C gives a product mixture which has the following composition after removal of unconverted phenol:

2-*tert*-butylphenol	39.7 %
4-*tert*-butylphenol	38.5 %
2,4-di-*tert*-butylphenol	21.4 %
highboilers	0.4 %

2-*tert*-Butylphenol is obtained in a purity of 99 % by distillation; 4-*tert*-butylphenol and 2,4-di-*tert*-butylphenol are marketable byproducts.

2-*tert*-Butylphenol is also formed with relatively high selectivity by reaction of phenol and isobutene over a γ-Al_2O_3-catalyst that has been tabletted with 10 % graphite and preconditioned by heating to 650 °C in an air stream. Phenol and isobutene conversions are 52 and 56 % at 150 – 160 °C, a molar ratio phenol : isobutene of 1 : 1, a pressure of 3.5 MPa, and a residence time of 1 h. The selectivity for 2-*tert*-butylphenol is 88 % based on phenol conversion; 4-*tert*-butylphenol (2.5 %) and 2,4-di-*tert*-butylphenol (5 %) are formed as byproducts. *tert*-Butyl phenyl ether [6669-13-2], *bp* 185 °C, is isolated as a byproduct (or intermediate). The amount of *tert*-butyl phenyl ether formed decreases with increasing residence times and reaction temperatures, and increases with age of catalyst. The ether can be recycled to the reaction zone.

4-tert-Butylphenol is obtained by reaction of phenol with isobutene at normal or slightly elevated pressure and ca. 80 – 140 °C in the presence of strongly acidic catalysts such as sulfuric [197] or phosphoric acids [198], boron trifluoride [199], activated clays [200-202], [209], zeolites [207], [208] or strongly acidic ion-exchange resins [203-206]. 4-*tert*-Butylphenol is obtained in ca. 70 % yield if *tert*-butyl phenyl ether is heated to 100 °C in the presence of a clay catalyst that has been activated with sulfuric acid [209]. Silica – alumina (75 % SiO_2) which has been sintered at 600 °C is said to catalyze isomerizations – trans-alkylations. Mixtures of phenol with 2-*tert*-butylphenol and 2,4-di-*tert*-butylphenol give 4-*tert*-butylphenol at 165 °C [210]. In the industrial process (Fig. 1), dehydrated strongly acidic sulfonated polystyrene – polydivinylbenzene ion-exchange resins of the macroporous form (⟶ Ion Exchangers) are employed which are placed on supporting sieves in column-type reactors. For maximum yields two reactors in series, held at different temperatures, must be used. The first reactor, where the exothermic alkylation takes place (– 90 kJ per mole isobutene reacted), is held at 90 – 100 °C; the second reactor (isomerization – transalkylation reactor) is held at 120 °C. (Isomerization and transalkylation reactions are thermoneutral to slightly endothermic.) The reactants are introduced to the top of the first reactor in a phenol – isobutene molar ratio of 1.4 : 1. Composition of the reaction products leaving the alkylation and the isomerization – transalkylation zones are given in Table 6. The reaction product leaving the isomerizer is worked up by continuous distillation under reduced pressure (4 – 10 kPa). A flow sheet of the industrial process [203] is depicted in Figure 1. Product yield is ≥ 95 % and product purity is > 98 %. 2,4-Di-, 2,4,6-tri-*tert*-butyl-, and 4-*tert*-octylphenol are formed as byproducts in the 4-*tert*-butylphenol production process. Their proportion increases with decreasing phenol – isobutene molar ratio and/or less stringent reaction conditions. 2,4-Di-*tert*-butylphenol can be made from phenol [211] or 4-*tert*-butylphenol [212] by alkylation with isobutene under mild reaction conditions and in the presence of small amounts of sulfuric acid at temperatures below 80 °C. 2,4,6-Tri-*tert*-butylphenol can be obtained from either of the three aforementioned phenols under these reaction conditions [213].

Table 6. Composition (wt %) of a phenol – isobutene alkylation product. Catalyst: cation-exchange resin; molar ratio 1.4 : 1 (phenol – isobutene)

Component	Alkylation	Isomerization–transalkylation
Isobutene	0.19	0.07
Phenol	30.17	22.16
4-*tert*-Butylphenol	33.92	75.08
2-*tert*-Butylphenol	10.19	1.62
2,4-Di-*tert*-butylphenol	23.71	0.82
2,4,6-Tri-*tert*-butylphenol + 4-*tert*-octylphenol	0.41	0.22

Figure 1. 4-*tert*-Butylphenol plant

a) Alkylator; b) Cooler; c) Isomerizer-transalkylator; d) Cooler; e) Distillation (phenol, 2-*tert*-butylphenol); f) Distillation; g) Vaporizer (2,4-di-*tert*-butylphenol recovery)

3-tert-Butylphenol is obtained from (1) 4- or 2-*tert*-butylphenol [214], [215], or (2) mixtures of 2,4- and 2,6-di-, or 2,4,6-tri-*tert*-butylphenol with phenol by heating to 170 – 200 °C in the presence of acid-activated clays [216], (synthetic) silica – alumina, modified zeolite of the Y-type [217], [218], or trifluoromethanesulfonic acid [219]. In the equilibrium state the monoalkylated fraction contains ≥ 70 % 3-*tert*-butylphenol and ca. 20 % of the 4-isomer; the dialkylated fraction contains ca. 80 % 3,5-di-*tert*-butylphenol [217]. A selective debutylation of the 4-isomer can be achieved. Thus, heating a 70 : 30 mixture of 3- and 4-*tert*-butylphenols to 160 – 170 °C for 5 h, after addition of 1 – 2 wt % H_2SO_4, followed by neutralization of the mineral acid and washing, yields 3-*tert*-butylphenol in > 90 % purity [220].

3-*tert*-Butylphenol can also be synthesized by heating 2-chloro-*tert*-butylbenzene with potassium-*tert*-butylate in *tert*-butanol to 240 °C for 4 h in an autoclave [221].

3,5-Di-tert-butylphenol is formed by heating isomeric mixtures of di-*tert*-butylphenols with acid-activated clays to 175 – 190 °C [222]. 3-*tert*-Butylphenol and/or 3,5-di-*tert*-butylphenol (depending on the chosen degree of alkylation) are obtained by reaction of phenol with isobutene at –78 to +25 °C in hydrofluoric acid [223]. Rearrangements of mono-*tert*-butylphenols in hydrofluoric acid as the solvent have been studied [224].

2,6-Di-tert-butylphenol (and 2-*tert*-butylphenol) is produced from phenol and isobutene in the presence of aluminum phenolate which is homogeneously dissolved in the phenol. The process, which has considerable industrial importance, was originally developed by Bayer [225].

Batchwise processes are preferred for industrial production using a stainless steel stirred-tank reactor provided with an efficient cooling device, e.g., an internal cooling coil. The reactor is charged with molten phenol, and flushed with pure nitrogen to remove all atmospheric oxygen. Metallic aluminum (1 wt %) in the form of granules or powder is added, and the reactor is heated to 120 – 180 °C for 0.5 – 1 h until the metal has dissolved to form aluminum phenolate under evolution of hydrogen which is vented. After cooling to 100 °C, liquid isobutene (1.8 – 2 mol per mole of phenol) is introduced into the reactor with stirring. During the reaction time of about 2 h, the pressure rises from 0.1 – 0.4 MPa to ca. 1.5 MPa. After stirring for a further 30 min, the pressure decreases to about 0.5 MPa. The reactor is depressurized and the reaction mixture is carefully washed with dilute sodium hydroxide and water. Rectification in vacuum yields about 75 % 2,6-di-*tert*-butylphenol, 10 % 2-*tert*-butylphenol, and a distillation residue consisting mainly of 2,4,6-tri-*tert*-butylphenol. 2-*tert*-Butylphenol can be recycled to the reactor. If desired, a higher amount of the monoalkylated phenol can be produced as a marketable product by using less than 1.8 mol isobutene per mole of phenol. The composition of the reaction products is dependent on the amount of isobutene used (see Table 7).

Table 7. Compositions (wt %) of phenol alkylation products using aluminum triphenolate as the catalyst (1 wt % Al dissolved in the educt phenol)

Component	Molar ratio isobutene : phenol	
	1.8	2.1
Phenol	4.4	0.6
2-*tert*-Butylphenol	10.3	1.7
4-*tert*-Butylphenol		0.2
2,6-Di-*tert*-butylphenol	73.5	75.9
2,4-Di-*tert*-butylphenol	2.2	0.9
2,4,6-Tri-*tert*-butylphenol	9.6	19.4

Exact control of temperature is important during the alkylation reaction, because at temperatures much lower than 100 °C *tert*-butyl phenyl ether formation prevails, whereas at higher temperatures ortho selectivity is progressively lost.

Industrially, the classical process provides an overall selectivity of about 85 %. Improvements have been proposed. According to an invention of Ethyl [226], selectivity can be as high as 95 % if 2-*tert*-butylphenol is used as starting material instead of phenol and if aluminum tris(2-*tert*-butylphenolate) is used as catalyst which is prepared in situ by reaction of 2-*tert*-butylphenol with triethylaluminum (ethane is evolved and vented). The reaction temperature should be preferably 0 – 10 °C. *tert*-Butyl phenyl ether is not formed because the catalyst is not acidic. The process is advantageous for producers that have an independent source of 2-*tert*-butylphenol. A simpler nonaqueous workup procedure has also been described [227]. Addition of small amounts of glycols and glycol ethers to the reaction mixture safely deactivates the aluminum phenolate catalyst and allows for direct recovery of products by distillation. Disposal of alkaline wash waters that are contaminated by phenolic bodies is therefore unnecessary.

Aluminum phenolate catalysis can be applied to produce 2-methyl-6-*tert*-butylphenol from *o*-cresol and isobutene.

Mono- and dibutylations of mixed *m*- and *p*-cresols, and of mixed 2,4- and 2,5-xylenols with gaseous or liquefied isobutene are carried out industrially in the presence of concentrated sulfuric acid (0.5 – 2 wt %). In the first step the corresponding phenolsulfonic acids are formed as the actual alkylation catalysts. A water content of more than 0.1 % in the educt phenols can be compensated for by using a higher proportion of sulfuric acid or by using oleum. Reactions occur at 50 – 80 °C and atmospheric to slightly elevated pressures.

For monobutylation of cresols an isobutene –cresol molar ratio of 0.7 – 1 is applied; the maximum yield of 80 % is obtained at a molar ratio of 1 [228], [229]. *p*-Cresol is converted to 2-*tert*-butyl-4-methylphenol (with some 2,6-di-*tert*-butyl-4-methylphenol), whereas *m*-cresol forms 2-*tert*-butyl-5-methylphenol (and some 4,6-di-*tert*-butyl-3-methylphenol). 4-*tert*-Butyl-3-methylphenol is formed from *m*-cresol under very mild, kinetically controlled conditions (very little H_2SO_4, < 40 °C) [230]. *o*-Cresol gives a mixture of 6-*tert*-butyl-2-methyl- and 4-*tert*-butyl-2-methylphenols, along with some 4,6-di-*tert*-butyl-2-methylphenol. The butylation products are usually worked up by neutralization of the catalyst with a slight excess of concentrated sodium hydroxide solution and subsequent distillation. Unconverted cresols and dibutylated compounds are recycled. The yield of monobutylated products is ≥ 90 %.

6-*tert*-Butyl-3-methylphenol can also be made by transbutylation of *m*-cresol with 4,6-di-*tert*-butyl-3-methylphenol, which is an intermediate of the *m/p*-cresol separation process (see below). The transbutylation is achieved by heating the mixture to 80 – 100 °C in the presence of acid-activated clays [231].

4-*tert*-Butyl-3-methylphenol is obtained only with difficulty. It can be formed by controlled debutylation of 4,6-di-*tert*-butyl-3-methylphenol by heating with the phenolates of aluminum [232] or (better) of zirconium [233], [234] under reflux conditions. Trans- and debutylation mixtures are worked up by fractionation, after deactivation of the catalyst by addition of alkali. 4-*tert*-Butyl-3-methylphenol can then be separated from 2-*tert*-butyl-5-methyl- and 2,6-di-*tert*-butyl-3-methylphenols because of its solubility in alkali [235].

5-*tert*-Butyl-3-methylphenol can be prepared by isomerization of 2-*tert*-butyl-5-methylphenol using substantial quantities of aluminum chloride at 30 °C [236].

2,6-Di-*tert*-butyl-4-methylphenol, frequently abbreviated as BHT (butylated hydroxytoluene), is a widely used antioxidant (⟶ Antioxidants – Hindered Phenols). Production of BHT involves reaction of pure and anhydrous (< 0.1 wt % H_2O) *p*-cresol with two or slightly more than two moles of isobutene in the presence of 2 wt % concentrated sulfuric acid at 70 °C and at an isobutene partial pressure of ca. 0.1 MPa. The reaction time is about 5 h. The reaction mixture contains about 95 % of BHT; some monobutylated phenols are formed as byproducts [237]. The usual workup procedure includes removal of acid by several washings with water at 70 °C, crystallization of the crude product, and a recrystallization from ethanol – water. The mother and washing liquids are first distilled at normal pressure for recovery of the ethanol. The remaining still bottoms separate into (1) an organic phase which is distilled under vacuum to recover 2-*tert*-butyl-4-methylphenol (to be recycled); and (2) an aqueous phase which is subjected to heat treatment (200 °C) to hydrolyze alkylphenolsulfonic acids into alkylphenols (which are recycled) and dilute sulfuric acid (which is neutralized and discarded) [238].

Alternatively, *m-/p*-cresol mixtures which cannot be separated by distillation, are first dibutylated and, after neutralization of the acid catalyst, are fractionated under vacuum to yield 2,6-di-*tert*-butyl-4-methylphenol (*bp* 147 °C at 2.66 kPa) and 4,6-di-*tert*-butyl-3-methylphenol (*bp* 167 °C at 2.66 kPa). The latter is subsequently reconverted to *m*-cresol by heating with 1 wt % oleum at 160 – 200 °C. The butyl group in the 4-position is eliminated first to yield 2-*tert*-butyl-5-methylphenol as intermediate. If required, this compound can be recovered by distillation of the partially debutylated product after neutralization of the acidic catalyst.

Several syntheses for 2,6-di-*tert*-butyl-4-methylphenol have been developed which are not based on *p*-cresol. At Shell, 2,6-di-*tert*-butylphenol was condensed with formaldehyde to yield 4,4′-methylenebis(2,6-di-*tert*-butylphenol) [118-82-1] which was subsequently heated to 200 °C with NaOH – methanol to give BHT in 80 % yield [239]. This synthesis can be conducted in one step by heating 2,6-di-*tert*-butylphenol with formaldehyde in the presence of NaOH – methanol [240]. In the Soviet Union, 2,6-di-*tert*-butyl-4-dimethylaminomethylphenol [88-27-7] (a Mannich base) is produced from 2,6-di-*tert*-butylphenol, formaldehyde, and dimethylamine, which in turn can be hydrogenated (Raney nickel, 120 °C) to give BHT in excellent yields [241], [242].

According to an invention of Ethyl, primary straight-chain alkyl groups can be introduced to the (ortho- or) para-position of phenols by heating them with *n*-alcohols that are presaturated with potassium hydroxide. However, this process does not take place with methanol. 2,6-Di-*tert*-butyl-4-ethylphenol [4130-42-1] and 4-butyl-2,6-di-*tert*-butylphenol [5530-30-3] became available by this “alkaline alkylation method” [243].

Mixtures of 2,4- and 2,5-xylenol can be alkylated with isobutene in the presence of concentrated sulfuric acid at 40 – 60 °C [244], [245]. 2,4-Xylenol reacts faster than 2,5-xylenol. Usually the reaction is terminated when all the 2,4-xylenol is converted. Fractionation of the neutralized and washed product mixture yields unconverted 2,5-xylenol, 6-*tert*-butyl-2,4-dimethylphenol, and a certain amount of the higher boiling 4-*tert*-butyl-2,5-dimethylphenol. Alternatively, the reaction mixture is first washed with dilute alkali to remove unchanged 2,5-xylenol (and, if present, 2,4-xylenol) and its mono-*tert*-butyl derivative. The insoluble residue is then distilled to give 6-*tert*-butyl-2,4-dimethylphenol [245].

Uses. *2-tert-Butylphenol* is a starting material for the synthesis of antioxidants and agrochemicals. Fragrance compounds are made from *cis*-2-*tert*-butylcyclohexanol [7214-18-8] which is obtained by hydrogenation of 2-*tert*-butylphenol in the presence of Pd – Al_2O_3 or Ru – Al_2O_3 catalysts [246]. Thermodynamic aspects of the stereoselective hydrogenation have been studied [247]. The acetate of the cis isomer [20298-69-5] has an orris-like fragrance.

3-tert-Butylphenol has found little if any commercial application. *4-tert-Butylphenol* is used on a large scale for the production of a variety of phenol – formaldehyde resins (⟶ Phenolic Resins – Aldehydes). If used as the single phenolic component, oil-soluble resins result; if used in admixture with phenol and *m*-cresol, resins with controllable cross-linking are obtained. These resins, which are applied as binders in surface coatings, lacquers, and varnishes, have good air-drying properties and durability against the deteriorating influences of light, weather, and chemicals. 4-*tert*-Butylphenol-derived novolac resins with low viscosity are used as tackifiers for oil-extended SBR – natural rubber blends [248] and as plasticizers for cellulose acetate. Under slightly modified conditions, formaldehyde and 4-*tert*-butylphenol (as well as other 4-alkylated phenols) condense to form cyclic condensation products called calixarenes because of their beaker- or cup-like shape [249], [250]. These compounds possess clathrating properties for cations.

R = *tert*-butyl, higher alkyl; *n* = 4, 6, 7, 8

An oil-soluble calixarene (R = *n*-hexyl, *n*=6) [117397-61-2] is a very efficient extraction agent for uranyl ions from aqueous solutions [251].

4-*tert*-Butylphenol has antioxidant properties and is used as a stabilizer in rubber and chlorinated hydrocarbons, and, formerly, in soaps. The esters of 4-*tert*-butylphenol with phosphorous and phosphoric acids are UV stabilizers for plastics and lacquers. Esters of 5-*tert*-butylsalicylic acid [16094-31-8], which is obtained from 4-*tert*-butylphenol by Kolbe synthesis, are used for the same purpose. 4-*tert*-Butylphenol serves as a chain-length regulator in the production of polycarbonate resins.

The alkoxylates (i.e., reaction products with alkylene oxides) of 4-*tert*-butylphenol are emulsifiers and wetting agents which can also act as demulsifiers, e.g., in crude oil. Hydrogenation of 4-*tert*-butylphenol yields *cis*- and *trans*-4-*tert*-butylcyclohexanols [98-52-2], whose esters with acetic acid are widely used as a substitute for lemon grass oil, especially in soap perfumes. 4-*tert*-Butylcyclohexanone [98-53-3] has a strong camphor-like odor and is used in scenting detergents and soaps.

The main use of *2,4-di-tert-butylphenols* is in the manufacture of its triphosphite [31570-04-4] that is employed as a (co-)stabilizer for poly(vinyl chloride), and of its benzotriazole derivatives that are used as UV absorbers in polyolefins.

2,6-Di-tert-butylphenol is an indispensable building block in the synthesis of higher molecular mass antioxidants and light-protection agents for plastics, especially polyolefins. Frequently used intermediates are 3,5-di-*tert*-butyl-4-hydroxybenzyl alcohol [88-26-6] (**3**), 3,5-di-*tert*-butyl-4-hydroxybenzyl chloride [955-01-1] (**4**), methyl-3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)- propionate [6386-38-5] (**5**), and 3,5-di-*tert*-butyl-4-hydroxybenzoic acid [1421-49-4] (**6**). These compounds are prepared from 2,6-di-*tert*-butylphenol by mild hydroxymethylation (**3**) [252],

chloromethylation (**4**) [253], conjugate addition to methyl acrylate (**5**) [254], and carboxylation with carbon dioxide (**6**) [255]. 2,6-Di-*tert*-butylphenol reacts with formaldehyde to give 4,4′-methylenebis(2,6-di-*tert*-butylphenol) [118-82-1], an effective antioxidant for lubricating oils.

In the 1980s much research was focused on the oxidative coupling of 2 molecules of 2,6-di-*tert*-butylphenol to form 3,3′,5,5′-tetra-*tert*-butyldiphenoquinone which is then reduced to the corresponding 3,3′,5,5′-tetra-*tert*-butyl-4,4′-diphenol [2455-14-3]. After removal of the butyl groups this compound yields 4,4′-dihydroxydiphenyl [92-88-6] which is a building block for thermoresistant polymers.

2,4,6-Tri-tert-butylphenol is the starting material for the synthesis of 2,6-di-*tert*-butyl-4-methoxyphenol [489-01-0] which is a powerful antioxidant. The first step involves oxidation of 2,4,6-tri-*tert*-butylphenol with Cl_2 in methanol in the presence of Na_2CO_3 followed by debutylation with sulfuric acid in methanol.

Monotert-butyl derivatives of m- and p-cresol are precursors for a number of commercially important antioxidants and light protection agents of the bisphenol and thiobisphenol type. Examples are 2,2′-methylenebis(6-*tert*-butyl-4-methylphenol) [119-47-1], 4,4′-methylenebis(6-*tert*-butyl-3-methylphenol) [2872-08-4], as well as the corresponding 2,2′-thiobis(6-*tert*-butyl-4-methylphenol) [90-66-4] and 4,4′-thiobis(2-*tert*-butyl-5-methylphenol) [96-69-5].

An important UV absorber, 2-(3-*tert*-butyl-2-hydroxyphenyl-5-methyl)-2 *H*-5-chlorobenzotriazole [3896-11-5], is produced from *2-tert-butyl-5-methylphenol*. 2-*tert*-Butyl-5-methylphenol is also used for the preparation of musk ambrette (6-*tert*-butyl-3-methyl-2,4-dinitroanisole) [83-66-9] which is a perfume fixative. The *N*-methylcarbamate of 5-*tert*-butyl-3-methylphenol is an insecticide. *2,6-Di-tert-butyl-4-methylphenol* (BHT) has found broad application as an antioxidant in polymers, in technical oils, as well as in edible oils and fat-containing foods where it retards the development of rancidity.

2,6-Di-tert-butyl-4-ethylphenol and *4-butyl-2,6-di-tert-butylphenol* are also used as antioxidants. *2-tert-Butyl-4-ethylphenol* is used as a precursor for the synthesis of other antioxidants.

Economic Aspects. The worldwide annual production capacity for *tert*-butylphenols is about 128 000 t, which can be broken down as follows:

Western Europe	53 000 t
United States	60 000 t
Japan	12 000 t

About 25 000 t/a of 2,6-di-*tert*-butylphenol and about 15 000 t/a of 2,4-di-*tert*-butylphenol are produced worldwide. The consumption of BHT as a stabilizer of polymers is about 15 000 t/a; the total consumption of BHT is higher by a factor of 2 – 3.

Toxicology and Occupational Health. Toxicological data for butylphenols are listed in Table 8. 4-*tert*-Butylphenol was found to cause leucoderma, a depigmentation of the skin (vitiligo), in a few sensitive individuals [256], [257]. The condition is likely to be long-lasting and cannot be treated. The appearance of vitiligo is greatly reduced if skin contact is avoided and there is good ventilation. The MAK value for 4-*tert*-butylphenol is 0.08 mL/m^3 (0.08 ppm), equivalent to 0.5 mg/m^3.

Table 8. Toxicological data of *tert*-butylphenols

	LD_{50} (oral, rat),	Effect on	
	mg/kg	Skin	Eyes
2-*tert*-Butylphenol	868	severe irritation	cauterization
4-*tert*-Butylphenol	4000	moderate irritation	severe irritation
2,4-Di-*tert*-butylphenol	3250	moderate irritation	moderate irritation
2,6-Di-*tert*-butylphenol	9200	irritation not reported	irritation not reported

Storage, Packaging, Transportation. In the presence of atmospheric oxygen, *tert*-butylphenols, like other alkylphenols, are prone to discolorations which are enhanced under the influence of light, elevated temperatures, traces of heavy metals (copper, iron), dissolved alkali, and moisture. During storage and transportation these influences must be kept to a minimum. *tert*-Butylphenols are therefore stored under an atmosphere of pure nitrogen.

In the liquid (molten) state, *tert*-butylphenols are stored and transported in stainless steel containers under a blanket of nitrogen. 2-*tert*-Butylphenol is transported in road or rail tank cars and in 200 L drums. 4-*tert*-Butylphenol is transported in the liquid state in thermostated road or rail containers at a temperature of about 110 °C. In the solid state it is stored under nitrogen in polyethylene bags of about 20 kg weight each that are palleted to a maximum weight of 1 t. As a solid 4-*tert*-butylphenol must be stored at < 40 °C. 2,4-Di-*tert*-butylphenol is transported in thermostated road tank cars at a temperature of 70° in the liquid state and iron drums (200 L) are used for the solid material. Transport classifications

for butylphenols are given in Table 9.

1.5.6. *tert-Pentylphenols*

Properties. Only a few physical constants of the *tert*-pentylphenols are available (see Table 10). Synonyms for the *tert*-pentyl group are 2-methyl-2-butyl or *tert*-amyl.

Table 10. Physical properties of *tert*-pentylphenols

Name	CAS registry no.	*mp*, °C	*bp*, °C	
			101.3 kPa	2.66 kPa
2-*tert*-Pentyl-phenol	[3279-27-4]			124
4-*tert*-Pentyl-phenol	[80-46-6]	95	266	142
3-*tert*-Pentyl-phenol	[27336-20-5]			143[*]
2,4-Di-*tert*-pentylphenol	[120-95-6]	27		166
2,6-Di-*tert*-pentylphenol	[3279-20-7]		283	165

[*] At 3.33 kPa.

Production. *tert*-Pentylphenols are obtained from the reaction of phenol with 2-methyl-1-butene, 2-methyl-2-butene, and/or 3-methyl-1-butene in the presence of acidic catalysts, since methylbutenes isomerize to form the most stable cation which is the tertiary pentyl. When phenol and olefin are employed in equimolar amounts, and boron trifluoride [258], phosphoric acid [259], or strongly acidic ion-exchange resins are used as catalyst [260], yields as high as 90 – 95 % 4-*tert*-pentylphenol are obtained at 100 – 120 °C. With a molar excess of olefin, 2,4-di-*tert*-pentylphenol is also formed, especially if acid-activated clays are used as catalysts [261], [262]. The residual C_5-fraction of an isoprene extraction plant can be used as a source of methylbutenes, provided that the cyclopentene fraction has been selectively hydrogenated on a Pd/Al_2O_3 catalyst prior to the alkylation [263].

Uses. Condensates of 4-*tert*-pentylphenol with formaldehyde are compounded with a drying oil and used as oil-soluble resins for application in surface coatings. Ethoxylation of 4-*tert*-pentylphenol forms surface-active substances which can be used as demulsifiers in crude oils. 2,4-Di-*tert*-pentylphenol is used for the preparation of photographic color developers, textile processing aids, and light stabilizers.

1.5.7. *Higher Alkylphenols*

Properties. This group of compounds includes alkylphenols containing at least one alkyl group with six or more carbon atoms. Physical data and specifications of higher alkylphenols of commercial importance are given in Table 11. The data represent standards set by producers with modern plants, e.g., Hüls. Higher alkylphenols are generally mixtures of isomers, due to the varying composition and chemical structure of the higher olefins employed for their production. The alkyl groups (C_8, C_9, C_{12}) are bonded via a tertiary (or, less frequently, secondary) carbon atom to the aromatic ring. In addition, the alkyl chains are branched.

Production. Higher alkylphenols are obtained by alkylation of phenol with "higher olefins" (⟶ Hydrocarbons – Olefins). Linear or branched α-olefins as well as linear or branched olefins with internal double bonds can be used as alkylating agents. Industrially, the most important higher olefins are

1. diisobutene, a 4 : 1 mixture of 2,4,4-trimethyl-1-pentene [107-39-1], *bp* 101.4 °C, and 2,4,4-trimethyl-2-pentene [107-40-4], *bp* 104.5 °C;

2. di-*n*-butene [25377-83-7] (mixture of octenes) with boiling range 116 – 126 °C;
3. propene trimer [27215-95-8] (mixture of nonenes) with boiling range 134 – 143 °C;
4. propene tetramer [9003-07-0] (mixture of dodecenes) with usual boiling range 185 – 205 °C; and
5. tri-*n*-butene [72317-18-1] (mixture of dodecenes) with boiling range 197 – 203 °C

A review of phenol alkylations with higher olefins has been published [264]. The preferred catalysts are ion-exchange resins, acid-activated clays, and synthetic aluminosilicates [265]. Occasionally boron trifluoride, *p*-toluenesulfonic acid, or phosphoric acid [198] are employed.

5-tert-Octylphenol, produced from phenol and diisobutene, consists mainly of 4-(1,1,3,3-tetramethylbutyl)phenol; commercial products always contain small amounts of the ortho isomer. The ortho – para isomer ratio depends on the alkylation conditions.

Boron trifluoride or its complexes with phenol or ethers are recommended as catalysts for the alkylation of phenol (and the cresols) with diisobutene and with other higher olefins. A reaction temperature of 50 – 85 °C and 1 – 2 wt % of BF_3 with respect to the phenol is required. A phenol – diisobutene molar ratio of 1.2 – 1.4 : 1 yields 90 –95 % octylphenol in less than 30 min at 50 °C [266]. Catalysis with BF_3 is suitable for batchwise production. Processes in continuously operated stirred-tank and tube reactors have been also described [267], [268]. The BF_3 catalyst can be removed from the reaction product by extraction with hot water [267] or by precipitation with milk of lime or concentrated ammonia [269]. Various procedures for a (partial) recovery of BF_3 have been described [268], [270], [271]. If further reactions are to be carried out with the primary alkylate, the removal of BF_3 can sometimes be postponed to a later stage, for example, if the alkylate is reacted with sulfur dichloride to give thiobisphenols [272].

Sulfonated polystyrene – polydivinylbenzene ion-exchange resins of the macroporous type are currently the catalysts of choice. They are applied in the form of beads of 0.3 – 1.5 mm in diameter. Column-type reactors filled with the catalyst resin are employed. The reaction of higher olefins with phenol is slower than that of isobutene, permitting easier control of the heat of reaction and the temperature gradient along the catalyst bed. Sometimes the catalyst activity is deliberately reduced by special measures. Nonetheless, high space velocities can be maintained because isomerization reactions are less important with higher olefins than with isobutene. Alkylations with higher olefins can be carried out at or close to normal pressure because of their high boiling points. Plants are similar to those described for the production of 4-*tert*-butylphenol (two column-type reactors in series, connected by a heat exchanger allowing for an intermediate cooling of the primary reaction product leaving the first reactor). Depending on the olefin, the alkylations are run adiabatically or close to isothermal conditions.

In a process specially designed for the production of 4-octylphenol [273], phenol and diisobutene (1.5 : 1 molar ratio, LHSV = 1 h^{-1}) are passed over an ion-exchange resin that is placed in a single column reactor. The reaction temperature is maintained at 100 – 105 °C by internal cooling coils. The resin, with an exchange capacity of ca. 400 meq H^+/100 g, is kept in the hydrated form (water content 10 – 15 %) by using phenol with a water content of 1 – 2 wt %. The water decreases the catalyst activity to a desired level, thus spreading the evolution of reaction heat and effectively suppressing the depolymerization of diisobutene, and, consequently, the formation of 4-*tert*-butylphenol. The reaction is carried out to a diisobutene conversion of about 95 %. The reaction product is distilled to remove water, diisobutene, and phenol and has the following composition: 0.5 – 1 % 4-*tert*-butylphenol, 2 – 3 % 2-*tert*-octylphenol, 93 – 96 % 4-*tert*-octylphenol, and 2 – 3 % dialkylphenols. The product can be purified further by fractionation under vacuum. 4-*tert*-Octylphenol is marketed in the liquid state in thermostated containers or in the form of pastilles or flakes.

Hüls, a major producer of higher alkylphenols in Western Europe, operates plants with a total annual capacity of 50 000 t that produce *nonylphenol* (the major product; propene trimer as alkylating olefin), *octylphenols* (di-*n*-butene and diisobutene as alkylating olefins), and *dodecylphenol* (propene tetramer and tri-*n*-butene as alkylating olefins). The process uses two equally-sized reactors in series which are both operated adiabatically. The heat of reaction that is generated in the first reactor is partially removed by a heat exchanger connecting the reactors. Macroporous, anhydrous ion-exchange resins of different acidity are employed as catalysts. The exchange capacities are about 80 meq H^+/100 mL in the first, and about 140 meq H^+/100 mL in the second reactor. The nonylphenol process is carried out as follows [274]:

Process Description. A mixture of phenol and propene trimer (molar ratio 1.7 : 1) is preheated to 70 °C and pumped to the top of the first reactor at an hourly rate of about 30 mass units per 1 mass unit of catalyst. The product leaving the first reactor with a temperature of 120 °C is cooled to 100 °C and led to the second reactor. The temperature of the reaction product leaving the second reactor is about 125 °C. Product compositions after the first and second step are (in wt %): propene trimer 28.9 and 3.8, phenol 46.1 and 27.5, nonylphenol 22.4 and 65.8, and dinonylphenol 2.6 and 2.9. The product of the second reaction step is worked up by distillation. Recovered phenol and propene trimer, as well as dinonylphenol, are recycled. Nonylphenol thus can be obtained in > 95 % yield. In general, the product purity is > 98 % and the ratio of 4 – 2-nonylphenol is ca. 90 : 10. A nonylphenol with a purity of 99.7 % and a 4 – 2-nonylphenol ratio of at least 95 : 5, obtained by careful distillation, is also being commercialized by Hüls. Dinonylphenol is formed as a byproduct and is normally recycled to the reaction zone. It can be isolated from the nonylphenol bottoms by further distillation under vacuum in 50 – 98 % purity, depending on market requirements.

Other nonylphenol processes that are performed in stirred-tank reactors, with a suspension of a finely ground ion-exchange resin as the catalyst, are becoming obsolete.

The production of *dodecylphenol* from phenol and propene tetramer is carried out with a comparatively large excess of phenol; molar ratios of 3 : 1 (phenol – propene tetramer) are common. In this case the alkylation can be conducted adiabatically at moderate temperatures, rising from about 50 °C to about 100 °C along the catalyst bed. An ion-exchange resin with an exchange capacity of 200 meq H^+/100 g serves as catalyst. Distillation of the reactor effluent and recyclization of unconverted phenol gives product yields of 90 – 95 %, depending on the quality of the propene tetramer.

Comparable yields of dodecylphenol are obtained if activated clays are used as catalysts. The reaction times, however, are considerably longer (several hours) with clays than with ion-exchange resins or boron trifluoride. Batch [275] and continuous [276] processes have been described. The batch process, working at 80 °C, uses a finely ground catalyst, that is maintained in suspension by stirring; the continuous process, which is operated at about 150 °C, uses a granulated catalyst in a column-type reactor.

Uses. Higher alkylphenols, mainly 4-octyl-, 4-nonyl-, and 4-dodecylphenols are predominantly reacted with ethylene oxide to form the corresponding ethoxylates that find many applications as technical nonionic surfactants. Extensive use in household detergents is prohibited because of insufficient biodegradability. Ethoxylates of nonylphenol with 4 – 5 ethylene oxide units are oil-soluble, those with 8 – 9 ethylene oxide units are used as wetting agents, e.g., in textile scouring. The main application of ethoxylates of dodecylphenol, dioctyl-, and dinonylphenols is the field of technical emulsifiers. Sulfonated dodecylphenol ethoxylates have been suggested as foam-stabilizing surfactants in miscible-gas enhanced oil recovery. The alkali salts of the esters of sulfuric and phosphoric acid with nonylphenol ethoxylates are anionic surfactants, which are used in metalworking and as emulsifiers for insecticides and herbicides.

Condensates of higher alkylphenols with formaldehyde are the basis for oil-soluble resins and lacquers.

Higher alkylphenols are employed as starting materials for the synthesis of antioxidants (⟶ Antioxidants – Phosphorus Compounds); an important example is tris(4-nonylphenyl) phosphite [31631-13-7]. Derivatives of 4-octylphenol are used as light stabilizers. 4-Octyl-, 4-nonyl-, and 4-dodecylphenol, as well as their mixtures with the corresponding di- and trialkylphenols are used as age-protection additives. Dodecylphenol is the starting material for lubricating oil additives: dodecylphenol is first sulfurized to give a bisphenol disulfide, and subsequent carboxylation (Kolbe synthesis) yields the corresponding salicylic acids. The calcium and magnesium salts of these acids are widely used as dispersants and antioxidants in lubricating oils.

Economic Aspects. The annual worldwide capacity for higher alkylphenols is about 540 000 t (Western Europe 166 000 t, Eastern Europe 110 000 t, North America 233 000 t, South America 7000 t, Japan 24 000 t).

Toxicology and Occupational Health. Octyl-, nonyl-, and dodecylphenols are relatively nontoxic; LD_{50} values (oral, rat) are 2000 mg/kg or higher. Contact with skin and eyes must be avoided because irritation or even burns can occur.

Storage, Packaging, and Transportation. Octyl-, nonyl-, and dodecylphenols will discolor if oxygen is not excluded. Storage and transportation facilities are therefore blanketed with nitrogen. The phenols are stored at 50 – 70 °C to permit sufficient pumpability.

The products are shipped in stainless steel or rail tank cars, or in 200 L drums. Transport classifications for higher alkylphenols are given in Table 12.

			320 (101.3)
4-Methyl-2-(1-methylcyclohexyl)phenol	[16152-65-1]	60 – 61	155 (1.33)
2,4-Dimethyl-6-(1-methylcyclohexyl)phenol	[77-61-2]	28 – 29	179 (2.93)

Production.
Cyclopentylphenols are produced by reaction of phenols with cyclopentene. Monoalkylation in the position ortho to the phenolic hydroxyl group is achieved with γ-Al_2O_3 as the catalyst at about 300 °C [254], whereas aluminum phenolate at 200 °C leads to 2,6-disubstitution [197], [277]. Disubstitution at the 2,4-positions occurs with boron trifluoride at 80 °C, with *p*-toluenesulfonic acid at 100 – 200 °C, or with active clays at about 150 °C [277]. Extended reaction times lead to isomerizations. Thus, dialkylation of *p*-cresol will give a mixture of 4-methyl-2,5-, 4-methyl-2,6-, and 4-methyl-3,5-dicyclopentylphenols after 15 h on active clay at 150 °C [277] or after 20 h on ion-exchange resins at 80 °C [278].

Cyclohexylphenols can be obtained from cyclohexene and phenols, under the conditions described for cyclopentylphenols. In addition to the aforementioned catalysts, phosphoric acid can also be used [237]. However, for reasons of price and availability cyclohexanol rather than cyclohexane is predominantly employed as the alkylating reagent. With aluminum silicates as catalysts, *p*-cresol reacts with cyclohexanol to give 2-cyclohexyl-4-methylphenol, whereas with phenol a mixture of 2- and 4-cyclohexylphenols is formed, which can be separated by distillation. Likewise, 2-methylcyclohexanol forms 4-methyl-2-(1-methylcyclohexyl)phenol with *p*-cresol and a mixture of 2- and 4-(1-methylcyclohexyl) phenol, with phenol. Alkylation of 2,4-xylenol with 2-methylcyclohexanol yields 2,4-dimethyl-6-(1-methylcyclohexyl)phenol. Industrially, cycloalkylphenols are produced by Bayer and ICI.

Uses.
2-Cyclopentylphenol is a precursor for toner components in xerography. The *N*-methylcarbamate derived from 3-cyclopentylphenol is used as an insecticide. 2,6-Dicyclopentyl-4-methylphenol is reported to be an efficient antioxidant [279].

2- and 4-Cyclohexylphenols are intermediates in the synthesis of pharmaceuticals and agrochemicals. The most important application of cyclohexylphenols is in the field of rubber chemicals (⟶ Rubber, 4. Chemicals and Additives). Thus, 2,4-dimethyl-6-(1-methylcyclohexyl)phenol is an excellent antioxidant that is especially suitable for white or light-colored rubber products. The condensates of 2-cyclohexyl-4-methylphenol and of 4-methyl-2-(1-methylcyclohexyl)phenol with formaldehyde are well-known nonstaining antioxidants used in natural and synthetic rubbers and in thermoplastics such as polyolefins, ABS resins, and high-impact polystyrene.

1.5.9. *Aralkylphenols*

Properties. Physical properties of selected aralkylphenols, described in this article, are listed in Table 14.

Table 14. Physical data of aralkylphenols

Name	CAS registry no.	*mp*, °C	*bp*, °C
2-Benzylphenol	[28944-41-4]	53 – 54.5	312
4-Benzylphenol	[101-53-1]	83 – 85	198 – 200 (1.33 kPa)
p-Cumylphenol	[599-64-4]	70 – 73	335

Production. Mixtures of *2-* and *4-benzylphenols* (ratio about 3 : 2) are obtained by heating benzyl chloride in an excess of phenol to 150 °C. The product mixture is obtained in 50 % yield if a molar ratio phenol – benzyl chloride of 2 : 1 is used; with a ratio of 10 : 1 the yield is 90 % of the theoretical yield [280]. Dibenzylphenols are the main byproducts. In the presence of Friedel –Crafts catalysts, preferably zinc chloride, the reaction rate is enhanced and the temperature can be reduced to below 100 °C [281]. The reaction product can be distilled. Generally, a separation of single isomers is not carried out. Cresols and xylenols can be benzylated in the same way. It was found, that the 3- and 4-benzylated derivatives of 2,6-xylenol are formed in parallel, not consecutive reactions [282].

Benzylations of phenolic compounds can also be achieved with benzyl alcohol under acid catalysis, preferably with *p*-toluenesulfonic acid. This has been used for ortho benzylation of bisphenols, whose para-positions are substituted [283].

(α-Methylbenzyl)phenols (styrenated phenols) [61788-44-1] are produced on a relatively large scale by reaction of phenol with styrene in the presence of sulfuric or *p*-toluenesulfonic acid or activated clays [284]. Phosphoric acid [285] and oxalic acid are also suitable catalysts. Depending on the amount of styrene applied, mixtures of mono-, di-, and tristyrenated phenol are obtained. As an example, when 2.1 mol styrene are slowly added, with stirring, to 1 mol phenol in the presence of 0.002 mol *p*-toluenesulfonic acid and at 110 – 120 °C, a product is obtained with less than 1 % of unreacted phenol, and with mono-, di-, and tristyrenated phenol concentrations of ca. 12, 46, and 41 %, respectively. Styrenated phenol is produced by many manufacturers and traded as a colorless to pale yellow viscous oil. Styrenations, as described, can also be applied to the common alkylphenols, such as the cresols and xylenols.

The styrenated phenols are predominantly used as such. Sometimes the reaction mixtures are used as intermediates. For example, the reaction product from *p*-cresol and styrene is first distilled under vacuum to remove unreacted starting materials, and the residue, mainly 4-methyl-2-(α-methylbenzyl)phenol, is condensed with aldehydes to give the corresponding bisphenols. The alkylation of partially styrenated phenol with isobutene or diisobutene is another example. After an appropriate workup, which includes neutralization or filtration of the catalyst and distillation of low-boilers, the product can be used as an antioxidant.

If α-methylstyrene is used instead of styrene, α, α-dimethylbenzyl groups (cumyl groups) are introduced into the phenol moiety [286], [287]. The catalyst of choice is an acidic ion-exchange resin arranged as a fixed bed in a column reactor as described for the production of the higher alkylphenols. Very pure *p*-cumylphenol can be obtained by this method, which is required for certain applications in the polymer field.

The alkylation of phenols with styrene, α-methylstyrene, and indene can also be performed with aluminum phenolate as catalyst [178], [288]. Substitution of phenol or *o*-cresol with styrene takes place predominantly in the ortho-position, whereas with α-methylstyrene, mainly para substitution is found.

p-Cumylphenol is formed to a certain extent during acid-catalyzed cleavage of cumene hydroperoxide (⟶ Phenol – Cumene Oxidation (Hock Process)). The high boiling still bottoms of phenol – acetone plants are a potential source for this aralkylphenol, which is, however, not exploited.

Uses. *2-Benzylphenol* and the mixtures of *2-* and *4-benzylphenol* have a certain commercial significance as disinfectants.

(α-Methylbenzyl)phenols (styrenated phenols) find extensive use as protective agents against thermal and oxidative aging of natural rubber and synthetic styrene – butadiene rubbers and latices, especially for application in white and light-colored articles.

4-(α, α-Dimethylbenzyl)phenol (*p*-cumylphenol) can be condensed with formaldehyde to give acid- and base-resistant resins. *p*-Cumylphenol of high purity, as supplied, for

instance, by Hüls, serves as a molecular-mass controlling component in the production of polycarbonates.

1.5.10. *Alkenylphenols*

Production.
4-Vinylphenol [2628-17-3] (*mp* 73.5 °C, sublimation range 70 – 80 °C at 0.004 kPa) can be obtained by gas-phase dehydrogenation of 4-ethylphenol at 550 – 600 °C and 0.1 MPa on an iron oxide catalyst and in the presence of steam and an aromatic hydrocarbon as diluents [289]. The alkenylphenol, which polymerizes readily, can be separated from the less acidic unconverted 4-ethylphenol by extracting the condensed reactor effluent with alkali at 30 °C [290]. The Maruzen Oil Co. is a supplier of 4-vinylphenol.

4-Isopropenylphenol [4286-23-1] and other 4-(alken-2-yl)phenols are obtained in yields up to 95 % of the theoretical by alkali-catalyzed cleavage of the corresponding bis(4-hydroxyphenyl)-alkanes (bisphenols) [291], [292]. As an example, bisphenol A is cleaved by heating to 190 –240 °C at a pressure of ≤ 5 kPa in the presence of 0.1 wt % sodium hydroxide. This reaction is carried out on a small technical scale by Mitsui Toatsu. The resulting phenol – 4-isopropenylphenol mixture is removed from the resinous material by distillation, followed by separation of phenol by rectification. The residual material is a fairly stable mixture of oligomers of 4-isopropenylphenol [64054-77-9], consisting of ≥ 80 % of the linear dimers (**7**) and (**8**), with dimer (**7**) prevailing [293].

The addition of radical scavengers does not prevent the formation of dimers and oligomers, which show the reactive behavior of the underlying monomer in many consecutive reactions. When the oligomers are heated to 150 – 200 °C under slightly reduced pressure and the evolving vapors are absorbed in high-boiling alcohols (*n*-octanol or ethylene glycol), a solution of monomeric 4-isopropenylphenol with remarkable stability is obtained [294].

Alkylations of phenol with conjugated dienes take place primarily as 1,4-additions. However, these reactions are rarely carried out on an industrial scale. At low temperatures (20 – 25 °C), and with phosphoric or *p*-toluenesulfonic acid as catalyst, 1,3-butadiene and isoprene react to give the expected alk-3-en-2-ylphenols. These tend to undergo cyclization reactions: ortho-alkenylphenols cyclize to form chromans and para-alkenylphenols form indanols. A concise review on phenol alkylation with conjugated dienes has been published [295]. A modified aluminum phenolate catalyst has been described for the reaction of various phenols with 1,3-pentadiene to form the expected pent-3-en-2-ylphenols [296].

"Cardanol" [37330-39-5], also known as "anarcardol", is a mixture of meta-C_{15}-alkenylphenols, and is obtained by decarboxylation of anarcardic acid, which is the main constituent of cashew nut-shell oil. The alkenylphenols have been identified as 3-(penta-dec-8-en-1-yl)-, 3-(pentadeca-8,11-dien-1-yl)-, and 3-(pentadeca-8,11,14-trien-1-yl)phenols [297].

Uses. Mixtures of *4-isopropenylphenol oligomers* with phenol(s) and self-drying oils are used in the lamination of paper [293]. A hydroquinone synthesis has been suggested involving the addition of hydrogen peroxide to the double bond of 4-isopropenylphenol, followed by acid-catalyzed cleavage of the 4-hydroxycumene hydroperoxide.

4-Isopropenylphenol serves as the starting material for the synthesis of indanols (see below). *Cardanol* is a component of special phenol – formaldehyde resins, which have self-drying properties because of the unsaturated character of the C_{15}-substituent.

1.5.11. *Indanols*

5-Indanol [1470-94-6], *mp* 54 – 55 °C, *bp* 255 °C, is produced from indan [496-11-7] by a sulfonation – alkali-fusion process [298]. A synthesis for 1,1,3,3-tetraalkylindanols was developed by Bayer [299-301], which involves the reaction of isoolefins with secondary alkenylphenols (or compounds generating them under the reaction conditions) at 100 – 250 °C and in the presence of acidic catalysts. An example is the reaction of isobutene with bisphenol A in the presence of acid-activated clays which yields 1,1,3,3-tetramethyl-5-indanol [53718-26-6], *mp* 115 °C, *bp* (2.66 kPa) 156 °C, in a yield of 80 % of the theoretical, and 4-*tert*-butylphenol as a coproduct.

Uses. 5-Indanol is a precursor for the synthesis of drugs. 1,1,3,3-Tetramethyl-5-indanol and other alkylindanols are used as photochemicals [302].

[Top of Page]

2. Catechol

Toshikazu Hamamoto and Sumio Umemura

Catechol [120-80-9], (pyrocatechol, 1,2-dihydroxybenzene, 1,2-benzenediol), $C_6H_4(OH)_2$, M_r 110.11 is a crystalline compound with a phenolic odor. It was first obtained in 1839 by REINSCH by dry distillation of catechin. Currently, it is produced industrially from phenol. It is mainly used as raw material for the synthesis of polymerization inhibitors, perfumes, drugs, pesticides, dyes, in fur dyeing and leather tanning, as well as in photographic developers, deoxygenating agents, and analytical reagents.

Occurrence. Catechol has been found in, e.g., crude beet sugar, crude wood tar, some species of eucalyptus, onion, and coal. Catechol and many of its derivatives are obtained by dry distillation and other processes from, e.g., tannin, lignin, woods, and bituminous coal. It also occurs in tobacco smoke and is present in human and horse urine in the form of its sulfuric ester.

2.1. Physical Properties

Catechol forms colorless monoclinic crystals. It sublimes, is steam volatile, and discolors in air or light. It readily dissolves in cold and warm water and in cold and warm hydrophilic organic solvents (e.g., ethanol and acetone). Catechol is readily soluble in warm, but only sparingly soluble in cold hydrophobic solvents (e.g., benzene and chloroform). Physical properties of catechol may be summarized as follows [303]:

mp	104 – 105 °C
bp (at 0.1 MPa)	246 °C

d_4^{15}	1.37
d_4^{121} (fusion)	1.15
Solubility in water	
at 15 °C	25 g/100 g solution
at 20 °C	31.2 g/100 g solution
at 100 °C	98.2 g/100 g solution
Specific heat	
at 25 °C	0.14 kJ mol^{-1} K^{-1}
at 104.3 °C (fusion)	0.24 kJ mol^{-1} K^{-1}
Heat of fusion	22.78 kJ/mol
Heat of sublimation at 36 °C	80.81 kJ/mol
Heat of vaporization	103.6 kJ/mol
Heat of formation	1.2 kJ/mol
Flash point (closed cup)	127 °C
Dissociation constant	
K_1 (18 °C)	3.3×10^{-10}
K_1 (30 °C)	7.5×10^{-10}
K_2 (30 °C)	8.4×10^{-13}
Vapor pressure	
168 °C	10 kPa
188 °C	20 kPa
211 °C	40 kPa
235 °C	80 kPa

2.2. Chemical Properties

Catechol gives a green coloration with iron-(III) chloride and turns red upon addition of a small amount of sodium hydroxide or ammonia. These colorations are specific for catechol and can be used for its detection and identification. Catechol can form stable coordination compounds with almost all metals and is therefore used as an analytical reagent for metals. Catechol is a weak acid and forms mono- and disalts with alkali hydroxides or carbonates. Many heavy metal salts of catechol, in particular its lead salts, are virtually insoluble in water. Thus, the reaction of catechol with lead acetate is used for quantitative analysis and separation of catechol from its isomers hydroquinone and resorcinol. Catechol is the strongest reducing agent of the three benzenediol isomers and can react with a solution of heavy metal salts to form fine precipitates of the elemental metals. 1,2-Benzoquinone is formed by careful oxidation of catechol with silver oxide or silver carbonate on celite. *cis,cis*-Muconic acid monomethyl ester [61186-96-7] can be obtained by oxidative cleavage of catechol with oxygen in the presence of copper(I) chloride and methanol [304].

Catechol undergoes many typical reactions of phenol. It reacts with acyl halides to form the corresponding mono- and diesters, which are converted into phenolic ketones by Fries rearrangement with aluminum chloride as catalyst. An aldehyde group can be introduced into the aromatic nucleus by Reimer – Tiemann reaction with chloroform and alkali, or by the addition of glyoxylic acid and subsequent oxidative decarboxylation.

Mono- and diethers of catechol can be prepared by the usual methods. Catechol can undergo cyclization reactions because of its two adjacent hydroxyl groups. It reacts with dichloromethane to form methylenedioxybenzene and with bis(2-chloroethyl)ether to yield dibenzo-18-crown-6-polyether [14605-55-1] [305]. Ammonolysis of catechol gives 2-aminophenol. Catechol couples with aryldiazonium salts to form azo compounds, which can be reduced to 4-aminocatechol.

Catechol forms bis(dihydroxyphenyl)methane by condensation reaction with formaldehyde, and polycyclic compounds (e.g., hystazarin and alizarin) by condensation with phthalic anhydride.

Ring mono-substitutions occur at the 3- and 4-positions. Catechol can thus be alkylated, halogenated, nitrated, carboxylated, and sulfonated.

Analysis. Catechol can be determined directly in mixtures containing phenol and other benzenediols by gas chromatography without prior separation [306].

2.3. Production

Catechol was formerly produced by low-temperature carbonization of coal, but this process is currently carried out only in rare cases.

Hydrolysis of 2-Chlorophenol.

Industrially, catechol can be produced by hydrolysis of 2-chlorophenol with an aqueous solution of barium hydroxide and sodium hydroxide. Barium is recovered as carbonate and recycled to the process by converting the carbonate into hydroxide, which complicates the process. Therefore, improved processes in which only caustic alkali is used have been developed. For example, 1 mol 2-chlorophenol is reacted with 2.3 mol 4 – 8 % sodium hydroxide solution in the presence of a copper(II) sulfate or copper(I) oxide at 190 °C for 3 h in a copper autoclave. The conversion of 2-chlorophenol is 96 – 99 %, the selectivity for catechol is 81 – 86 % [307]. The reaction mixture is then neutralized with sulfuric acid and the crude catechol formed is extracted, the solvent is recovered, and catechol is separated and purified by distillation. The industrial production of catechol was carried out by this method up to 1973.

Hydroxylation of Phenol. Catechol is currently manufactured together with hydroquinone by direct hydroxylation of phenol with peroxides. At present, three plants using this process are in operation worldwide; each plant uses a somewhat different type of peroxide or catalyst. As the reaction is exothermic and the benzenediols formed are more easily oxidized than phenol, the reaction is carried out in a large excess of phenol.

In France, *Rhône-Poulenc* react phenol with 70 % hydrogen peroxide (molar ratio 20 : 1) in the presence of phosphoric acid and catalytic amounts of perchloric acid at 90 °C; catechol and hydroquinone are obtained in a ratio of ca. 3 : 2 [308]. This reaction proceeds electrophilically and phosphoric acid serves as a masking reagent preventing side reactions (formation of resorcinol by a radical reaction which gives a lower yield) caused by trace amounts of metallic ions. After the reaction, phosphoric and perchloric acids are removed by washing with water, then the reaction mixture is simultaneously extracted by diisopropyl ether, distilled, and continuously separated.

Brichima SpA (now Enichem) in Italy uses heavy metal compounds (e.g., small quantities of ferrocene and/or cobalt salts) as catalyst and reacts phenol with 60 % aqueous hydrogen peroxide at 40 °C. Catechol and hydroquinone are produced in the ratio of 1.5 – 4.1 [309]. This reaction occurs via a free-radical chain mechanism and is thus very fast.

In Japan, *Ube Industries* produces catechol together with hydroquinone by hydroxylation of phenol with ketone peroxides formed in situ from a ketone and hydrogen peroxide in the presence of an acid catalyst [310], [311]. The process is carried out by adding a trace amount of acid (e.g., sulfuric or sulfonic acid), a small volume of ketone, and 60 % aqueous hydrogen peroxide to phenol at 70 °C. The ketone peroxide that is formed in situ reacts rapidly and electrophilically with phenol, and catechol and hydroquinone are obtained in a molar ratio of about 3 : 2 in more than 90 % yield (based on phenol reacted). When a solid acid such as clay is used as a catalyst, the molar ratio of catechol and hydroquinone is about 1 : 1 [312]. As only a small amount of catalyst is used, no corrosion occurs and the reaction mixture can be distilled without removing the catalyst after the reaction. The added ketone can be recycled to the process by recovering it by distillation.

The *separation and purification methods* used in the three aforementioned processes are basically the same. That is, the reaction mixture is separated by distillation in different distillation columns. Water is removed, low-boiling fractions (solvents, ketone etc.) and unreacted phenol are recovered and recycled, the catechol fraction is made into a flaked product, and hydroquinone is purified by recrystallization of the corresponding fraction from water.

Processes, in which hydroxylation of phenol is carried out in the presence of catalysts such as strong acids or sulfur dioxide with nonaqueous hydrogen peroxide solution, have been patented [313], [314].

Peracids formed in situ from carboxylic acids and hydrogen peroxide or synthesized by air oxidation of aldehydes are utilized as hydroxylating agents [315]. In the case of hydroxylation using peracetic acid (synthesized through autoxidation of acetaldehyde), chelating reagents and phosphates are used as additives which improve the yield of benzenediols. Nevertheless, because of problems such as complicated separation of products and corrosion of apparatus, the peracid processes have not been realized industrially.

Dehydrogenation of 1,2-Cyclohexanediol. Recently, a patent has been published claiming that catechol can be obtained in 90 % yield by dehydrogenation of 1,2-cyclohexanediol with a Pd/Te catalyst system at 300 °C [316]. Catechol is reportedly formed as the single product.

In addition, catechol may be obtained via the following synthetic routes: (1) alkali fusion of 2-phenolsulfonic acid and phenol-2,4-disulfonic acid; (2) oxidation of salicylaldehyde with

hydrogen peroxide in aqueous alkaline solution; (3) demethylation of guaiacol with hydrobromic acid or aluminum chloride; and (4) hydrolysis of 2-aminophenol using a hydrogen halide.

2.4. Uses

Catechol itself is used as a photographic developer, analytical reagent, and oxygen scavenger (antioxidant); most catechol is used in the form of its derivatives: guaiacol (2-methoxyphenol) [90-05-1] and veratrole (1,2-dimethoxybenzene) [91-16-7] can be synthesized by *O*-methylation of catechol. Vanillin (4-hydroxy-3-methoxybenzaldehyde) [121-33-5], derived from guaiacol is used as a flavoring agent. Ethylvanillin(3-ethoxy-4-hydroxybenzaldehyde) [121-32-4] derived from guethol (2-ethoxyphenol, a homologue of guaiacol) is not found in nature, and its flavor is 3 – 4 times stronger than that of vanillin. It is thus a valuable aroma compound. Eugenol (2-methoxy-4-allylphenol) [97-53-0], safrole (5-allyl-1,3-benzodioxole) [94-59-7], and piperonal [3,4-(methylenedioxy)benzaldehyde] [120-57-0], which can be prepared from the latter, are useful fragrances in perfumery.

In medicine, potassium guaiacol sulfonate (4-hydroxy-3-methoxy-benzenesulfonic acid monopotassium salt) [16241-25-1] and guaiacol glyceryl ether [3-(2-methoxyphenoxy)-1,2-propanediol] [93-14-1] are used as expectorants. L- α-Methyldopa (3-hydroxy- α-methyl-L-tyrosine) [555-30-6] and L-dopa (3-hydroxy-L-tyrosine) [59-92-7] derived from vanillin are used as an antihypertensive and as an antiparkinsonism drug, respectively. In addition, trimethoprim [738-70-5] derived from vanillin is used as an antiinfective; carbazochrome [69-81-8] and carbazochrome sodium sulfonate [51460-26-5] are used as hemostatics; papaverine [58-74-2] is used as an antispasmodic, vasodilator drug and smooth muscle relaxant.

Two important carbamate insecticides that are produced from catechol are used as agricultural chemicals — carbofuran [1563-66-2] (2,3-dihydro-2,2-dimethyl-7-benzofuranyl methylcarbamate, trade name Furadan), and propoxur [114-26-1] (2-isopropoxyphenyl-*N*-methylcarbamate, trade name Baygon) developed by Bayer.

4-*tert*-Butylcatechol [98-29-3], which is prepared by ring alkylation of catechol, is applied as a polymerization inhibitor during manufacturing and storage of monomers such as styrene and butadiene.

2.5. Economic Aspects

The consumption of catechol in the world is estimated to be about 20 000 t/a in 1990. It is assumed that 50 % of that is used as starting material for insecticides, 35 – 40 % for perfumery and drugs, and 10 – 15 % for polymerization inhibitors and others. As the vanillin process is changing from production using lignin in pulp waste liquor to the synthesis from catechol, the demand for catechol used in the production of vanillin is expected to increase in the future [317]. The market price of catechol in May 1990 was 4.2 – 5.7 $/kg [318].

2.6. Toxicology

Catechol is readily absorbed from the gastrointestinal tract and through the skin and readily metabolized and excreted into urine. General symptoms of catechol intoxication are similar to those of phenol intoxication. Administration of a large dose of catechol induces strong suppression of the central nervous system and long-term vascular hypertension. The prolonged contact of catechol with skin leads to eczematous dermatitis or ulcers. In addition, it causes severe eye irritation.

Comprehensive references exist on catechol toxicity [319]. Some characteristic values of catechol toxicity are as follows [320]:

LD_{50} (oral, rat)	3890 mg/kg
LDLo (subcutaneous, rat)	200 mg/kg
LD_{50} (subcutaneous, mouse)	247 mg/kg
Threshold limit value	5 ppm

[Top of Page]

3. Trihydroxybenzenes

Tadao Iwata, Hisaya Miki, Yasuhiro Fujita

3.1. Pyrogallol

Pyrogallol [87-66-1], $C_6H_3(OH)_3$, M_r 126.11 is generally called 1,2,3-trihydroxybenzene, 1,2,3-benzenetriol (IUPAC name), or pyrogallic acid. Pyrogallol was first isolated by SCHEELE by dry distillation of gallic acid (3,4,5-trihydroxybenzoic acid) in 1786. Pyrogallol derivatives occur in many natural products, such as tannin, anthocyanin, and alkaloids [321].

Physical Properties. Pyrogallol forms colorless needles or leaflets, the color gradually changes to dark gray on contact with air or light. It is soluble in water and polar solvents, and slightly soluble in chloroform and carbon disulfide. It sublimes without decomposition upon gradual heating. Important physical data are as follows:

mp	133 – 134 °C
bp (101.3 kPa)	309 °C (partial decomp.)
(17 kPa)	171 °C
d_4^4	1.453
Dissociation constant (20 °C)	
K_1	1.5×10^{-10}
K_2	4.5×10^{-12}
Solubility (25 °C)	
water	38 wt %
ethanol	50 wt %
pyridine	soluble
ether	45 wt %
benzene	slightly soluble
chloroform	slightly soluble
carbon disulfide	slightly soluble

Chemical Properties. Pyrogallol is the strongest reducing agent among the polyhydroxybenzenes. The basic aqueous solution quickly absorbs gaseous oxygen to form a dark brown precipitate. Because of this property, pyrogallol is often used for quantitative analysis of oxygen.

Reactions of pyrogallol are quite similar to those of phenols. The hydroxy groups are etherified and esterified by the conventional methods to give mono-, di-, and trisubstituted products. Heating of pyrogallol in aqueous potassium bicarbonate solution mainly gives pyrogallol-4-carboxylic acid (2,3,4-trihydroxybenzoic acid); gallic acid is formed as a byproduct. Formylation, acylation, and the Mannich reaction produce 4-substituted cyclohexenones as a major product. Bromination with bromine eventually yields 1,2,6,6-tetrabromocyclohexene-3,4,5-trione. Reaction with phosgene gives pyrogallol carbonate, and with thionylbromide 4,5,6-tribromopyrogallol. The highly sensitive color reactions of aqueous pyrogallol solution with heavy metal ions are useful for the quantitative analysis of metals. Precious metal ions (e.g., Ag^+, Au^{2+}, Hg^{2+}) are reduced to elemental metals.

A complex prepared from diethylzinc and pyrogallol is used for a catalyst for alternating polymerization of carbon dioxide and propylene oxide [322].

Production. Pyrogallol is commercially produced by decarboxylation of gallic acid, which is prepared by hydrolysis of tannin.

The reaction is carried out batchwise. A 50 % aqueous solution of gallic acid is heated to 175 – 200 °C in an autoclave. During the reaction, the pressure increases to 1.2 MPa. After the evolution of carbon dioxide is completed, the solution is cooled. The reaction proceeds quantitatively. Decolorization of the reaction mixture with charcoal followed by distillation gives a crude product which is purified by sublimation or vacuum distillation [323].

Pyrogallol is expensive to obtain because the starting material gallic acid is prepared from a natural product of limited availability. Therefore, new methods for producing gallic acid have been sought. Base-catalyzed condensation of trimethyl propane-1,2,3-tricarboxylate with the dimethyl ketal of mesoxalic acid, followed by hydrolysis and decarboxylation gives gallic acid in 74 % yield [324]. The reaction of the ketal and glutaric ester gives pyrogallol without generation of gallic acid [325].

Other methods for producing pyrogallol include oxidation of resorcinol with hydrogen peroxide [326], hydrolysis of 2,6-diamino-4-butylphenol [327], demethylation of 4-substituted 2,6-dimethoxyphenols [328], oxidation of 2,6-dimethylphenol [329], hydrolysis of 2,2,6,6-tetrachlorocyclohexanone [330], deoximation of 1,2,3-cyclohexanetrion-1,3-dioxime [331], and dehydrogenation of 1,2,3-trihydroxycyclohexane [332].

Uses. Pyrogallol is used in photography, lithography, and in hair dyes. It is also used as an antioxidant and stabilizer. The use of pyrogallol in the field of cosmetics and medicines is currently declining because of its pronounced toxicity.

Toxicology. Ingestion of pyrogallol may cause severe irritation. Toxicity data are as follows [333]:

LD_{50} (oral, mouse)	300 mg/kg
LD_{50} (subcutaneous, mouse)	566 mg/kg

3.2. Hydroxyhydroquinone

Hydroxyhydroquinone [533-73-3], $C_6H_3(OH)_3$, M_r 126.11 is usually called 1,2,4-trihydroxybenzene, 1,2,4-benzenetriol (IUPAC name), or hydroxyquinol. Its derivatives are found as ethers or quinoids in plants.

Physical Properties. Hydroxyhydroquinone forms colorless platelets or prisms that quickly colorize in air. It is soluble in water and polar solvents, and slightly soluble in chloroform and carbon disulfide. Important physical data are as follows:

mp	140.5 – 141 °C
Dissociation constant (20 °C)	
K_1	8.3×10^{-10}
K_2	1.5×10^{-12}
Solubility	
water	soluble
ethanol	soluble
pyridine	soluble
ether	soluble
benzene	slightly soluble
chloroform	slightly soluble
carbon disulfide	slightly soluble

Chemical Properties. Hydroxyhydroquinone is, like other phenols, a strong reducing agent. Its basic aqueous solution absorbs gaseous oxygen to produce black precipitates of the humic acid type. Hydroxyhydroquinone shows typical reactions of phenols. Derivatives of the tautomeric keto form are also known: halogenation of hydroxyhydroquinone, for example, gives 1,2,5,5-tetrahalocyclohexene-3,4,6-trione. Condensation with ethylacetoacetate produces dihydroxycoumarin; reaction with phthalic anhydride yields hydroxyhydroquinonephthalein. Monosubstitution of a hydroxy group by an amino group occurs easily at room temperature and gives 2,4-dihydroxyaniline [334].

Production. Hydroxyhydroquinone is synthesized by hydrolysis of 1,2,4-triacetoxybenzene, which is prepared by the acid-catalyzed reaction of *p*-benzoquinone with acetic anhydride [335].

Other production methods for hydroxyhydroquinone are oxidation of resorcinol with hydrogen peroxide [336] and Dakin oxidation of 2,4- or 3,4-dihydroxybenzaldehydes or 2,4- or 3,4-dihydroxyacetophenones with alkaline hydrogen peroxide solution.

Uses. Hydroxyhydroquinone is used as a stabilizer, antioxidant, polymerization inhibitor and in hair dyes.

Toxicology. Toxicity data are as follows [333]:

LDLo (intraperitoneal, mouse)	125 mg/kg
LD_{50} (subcutaneous, mouse)	500 mg/kg

3.3. Phloroglucinol

Phloroglucinol [108-73-6], $C_6H_3(OH)_3$, M_r 126.11 is also called phloroglucine, 1,3,5-trihydroxybenzene, 1,3,5-benzenetriol (IUPAC name), or cyclohexane-1,3,5-trione. In 1855, HLASIWETZ found phloroglucinol in the hydrolysis products of phloretin, which was obtained from the bark of fruit trees. The name phloroglucinol originates from the Greek and means “sweet bark”. Its derivatives (e.g., flavones, anthocyanides, and xanthins) are widely distributed in the plant kingdom.

Physical Properties. Phloroglucinol crystallizes in the anhydrous form or as the dihydrate. Recrystallization from water gives the dihydrate, which is colorless, oderless, sweet in taste, and forms rhombic crystals. The dihydrate is converted into the anhydrous form by heating at 110 °C. Phloroglucinol sublimes at higher temperatures with partial decomposition. Important physical data are as follows:

mp (anhydrous form)	218 – 220 °C
mp (dihydrate)	116 – 117 °C
Dissociation constant (30 °C)	
K_1	3.56×10^{-9}
K_2	1.32×10^{-9}
Solubility	
water	1 wt %
ethanol	9 wt %
pyridine	75 wt %
diethyl ether	soluble
benzene	slightly soluble

In conductometric titration, the behavior of phloroglucinol resembles that of benzenediols. The third proton is not dissociated. According to ^{1}H NMR, the dianion of phloroglucinol forms stable keto-type tautomers in solution. Phloroglucinol itself, however, is present in the enolic form, which has been confirmed by UV, IR, NMR, and X-ray spectra [337].

Chemical Properties. Because of the keto – enol tautomerism, phloroglucinol reacts to form triphenol derivatives and triketone derivatives.

Phloroglucinol behaves as a triketone, e.g., towards hydroxylamine to form the trioxime, and adds sodium bisulfite to yield the corresponding mono-, di-, and tri-substituted products. Triphenol behavior is shown in etherification and esterification that form mono-, di-, and trisubstituted phenols. Friedel – Crafts reaction and nitration also take place.

Phloroglucinol is also a reducing agent. The alkaline aqueous solution absorbs gaseous oxygen. The absorption of oxygen by phloroglucinol proceeds more slowly than by pyrogallol. Phloroglucinol reduces Fehling's solution and precious metal ions (e.g., Au^{2+}, Ag^{+}, and Pt^{2+}). Reaction with methyl iodide causes ring methylation under basic conditions. Reaction with aqueous ammonia produces 5-aminoresorcinol or 3,5-diaminophenol. Phloroglucinol forms phloroglucide upon heating. Hydrogenation gives 1,3,5-trihydroxycyclohexane. Coupling with diazonium salts takes place easily.

Production. Phloroglucinol can be prepared by various processes. 2,4,6-trinitrotoluene is oxidized with sodium dichromate to give 2,4,6-trinitrobenzoic acid, which is subsequently decarboxylated. The nitro groups are then reduced with iron – hydrochloric acid to form 1,3,5-triaminobenzene. Subsequent nucleophilic substitution of the amino groups by hydroxyl groups produces phloroglucinol. However, waste-disposal of the acidic filtrates which contain chromium and iron poses a problem [338].

In the 1980s, a process was developed to produce phloroglucinol from 1,3,5-triisopropylbenzene via the corresponding trihydroperoxide [339]. The yield is increased by addition of hydrogen peroxide to the reaction mixture in the acidolysis step [340]. Another method for producing phloroglucinol is the Beckmann rearrangement of triacetylbenzene trioxime followed by hydrolysis [322].

Other methods include Hofmann rearrangement of benzene-1,3,5-tricarboxylic acid triamide [342]; reaction of 1,3,5-tribromobenzene [343] or hexachlorobenzene [344] with alkoxide followed by acidolysis; and hydrolysis of 4-chlororesorcinol with potassium hydroxide [345].

Uses. Phloroglucinol is used as a coupler in diazotyping. Phloroglucinol and the diazo compound react with each other to form a large molecule which has a black color. In the drying process, the diazo and hydroxy compounds are both contained in the coating (⟶ Imaging Technology – Processing). Phloroglucinol is also used for photocopying [338].

Toxicology. Toxicity data are as follows [333]:

LD_{50} (intraperitoneal, mouse)	4050 mg/kg
LD_{50} (oral, mouse)	4550 mg/kg
LD_{50} (subcutaneous, mouse)	991 mg/kg

4. Bisphenols (Bishydroxyarylalkanes)

Hans-Josef Buysch

In this review bisphenols are defined as compounds consisting of two phenol nuclei linked by a hydrocarbon bridge.

History. The importance of bisphenols has increased continually with the growth of the plastics industry from about the end of the 1930s. They are used as intermediates for high-grade thermosets, thermoplastics, and raw materials for varnishes; and as antioxidants for rubber, plastics, oils, and fats. 2,2-Bis(4-hydroxyphenol)propane (bisphenol A), first described in 1891 by A. DIANIN, is by far the most important compound in this series. It has been produced industrially from phenol and acetone to be used as a starting material for epoxy resins since about 1945. The development of polycarbonates, the most important thermoplastics based on bisphenol A, began in the 1950s.

4.1. Physical Properties

Bisphenols are colorless, odorless substances, and most of them are solid at room temperature. The melting points of the most important bisphenols are between 100 and 200 °C [346]. Bisphenols are virtually insoluble in water. Their solubility in organic solvents is determined by their substituents. Whereas bisphenol A is only readily soluble in polar media such as ethers and alcohols, bisphenols with large aliphatic groups in the molecule are soluble in araliphatic and aliphatic hydrocarbons. The alkali salts of bisphenols are water-soluble. However, their solubility decreases drastically with increasing substitution. The boiling points of bisphenols are very high because of the size of the molecule and its polarity. For this reason and because of the decomposition frequently observed during boiling, bisphenols are rarely distilled. Some important physical properties of bisphenols are summarized in Table 15. Physical properties for the industrially important bisphenol A may be summarized as follows:

Density at 20 °C	1.04 g/cm^3
at 160 °C	1.065 g/m^3
Bulk density	0.492 g/cm^3
Heat of fusion	147 J/g
bp at 101.3 kPa	360 °C
at 1.4 kPa	240 °C
at 0.4 kPa	222 °C
Heat of varporization at 101.3 kPa	404 J/g
Flash point	227 °C
Ignition temperature	510 °C
Solubility in H_2O at 83 °C	0.344 wt %
Solubility in acetone, alcohol	good

Solubility in methylene chloride ca. 1 wt %

Table 15. Physical properties of some bisphenols

	CAS registry no.	Structural formula	Molecular formula	M_r	*mp*, °C	*bp*, °C
Bis-(4-hydroxyphenyl)methane	[*620-92-8*]	**9**	$C_{13}H_{12}O_2$	200.2	158	
2,2-Bis(4-hydroxyphenyl)propane (bisphenol A)	[*80-05-7*]	**10**	$C_{15}H_{16}O_2$	228.3	156–157	190 (130 Pa)
4,4-Bis(4-hydroxyphenyl)valeric acid	[*126-00-1*]	**11**	$C_{17}H_{18}O_4$	286.3	173	
2,2-Bis(4-hydroxy-3-methylphenyl)propane	[*79-97-0*]	**12**	$C_{17}H_{20}O_2$	256.3	136	
2,2-Bis(4-hydroxyphenyl)cyclohexane (bisphenol Z)	[*843-55-0*]	**13**	$C_{18}H_{20}O_2$	268.4	188	
2,2′-Methylene bis(6-*tert*-butyl-3-methylphenol)	[*119-47-1*]	**14**	$C_{23}H_{32}O_2$	340.5	131	
α,α′-Bis(4-hydroxyphenyl)-*p*-diisopropylbenzene	[*2167-51-3*]	**15**	$C_{24}H_{26}O_2$	346.3	196	230 (13 Pa)
Bis(2-hydroxy-3-cyclohexyl-5-methylphenyl) methane		**16**	$C_{27}H_{36}O_2$	392.6	128	
Bis(4-hydroxy-3,5-di-*tert*-butylphenyl)methane	[*118-82-1*]	**17**	$C_{29}H_{44}O_2$	424.7	154	

4.2. Chemical Properties

The chemical properties of the bisphenols are determined by the phenolic OH groups, the aromatic rings, and the alkyl bridge. They therefore undergo the same reactions as the corresponding substituted monophenols (esterification and etherification at the OH group, substitution and hydrogenation on the aromatic ring, see Section Chemical Properties). They are also suitable as building blocks for high molecular mass linear polyesters and polyethers because of their bifunctionality [346-348].

Bisphenols which are alkylated ortho to the OH group readily trap radicals and are therefore suitable as stabilizers (⟶ Antioxidants – Hindered Phenols).

Bisphenols fragment purely thermally, or better catalytically, according to:

Under hydrogenation conditions bisphenol A is cleaved to give 4-isopropylphenol [349]; alkali-catalyzed cleavage gives 4-isopropenylphenol [350] in good yields. Both compounds are difficult to obtain by other methods. The alkali-catalyzed cleavage of various bisphenols has been investigated [351]. The cleavage can also be catalyzed by acids to form indans and spirobisindans [352]:

The purely thermal cleavage is generally less straightforward [350].

4.3. Production

Bisphenols can be produced (1) by condensation of ketones or aldehydes with phenols, (2) by reaction of, e.g., diols or dihalides with phenols, and (3) by condensation of hydroxymethylphenols with phenols.

Condensation of Ketones or Aldehydes with Phenols. Acid- or alkali-catalyzed condensation of 1 mol ketone or aldehyde with 2 mol phenol yields bisphenols, whose aromatic nuclei are separated by one carbon [353]. Acetone and cyclohexanone give particularly smooth para addition and high yields of 4,4′-dihydroxydiphenylalkanes [350]:

Aldehydes generally react with un- and monosubstituted phenols to give mixtures of isomers and polynuclear phenols of the novolac type (⟶ Phenolic Resins). 2,4-, 2,5-, 2,6-, 2,3,6-, and 2,3,5,6-substituted phenols, however, react readily and often in excellent yields with aldehydes (particularly formaldehyde) to form the corresponding bisphenols [354-358]. These reactions are frequently alkali-catalyzed. In other cases, however, alkali gives less pure products and poorer yields [350], [358]. Highly alkylated bisphenols are also obtained by subsequent alkylation of preformed bisphenols in the presence of acid catalysts [359]. Suitable acid catalysts are hydrogen chloride, highly concentrated hydrochloric acid, sulfuric acid (up to 75 %), boron trifluoride, acid-activated clays and sulfonated cross-linked polystyrenes [349], [350], [360-364].

Cocatalysts containing SH groups e.g., thiols and mercaptoacids, are used to increase the reaction rate [349], [350], [362], [365], [366].

Organic solvents such as aromatic and chlorinated hydrocarbons or glacial acetic acid serve as the reaction medium. Aqueous emulsions may also be used. To prevent side reactions, the phenol which is being reacted must frequently be added in excess and thus functions simultaneously as the reaction medium.

Reaction of Diols, Diolefins etc. with Phenols. Bisphenols can also be produced by the acid-catalyzed reaction of diols and dihalides [364], [367], [368] or alkynes or allenes [369] with phenols. Divinylbenzenes react with phenols at elevated temperature without catalysts [370].

Condensation of Hydroxymethylphenols with Phenols. Unsymmetrical dihydroxydiphenylmethanes are formed by condensation of hydroxymethylphenols (from phenol and formaldehyde) with phenols with a different substitution pattern [357]. The synthesis of unsymmetrical bisphenols substituted at the central carbon atom can be achieved by alkylation of phenols with vinylphenols [346], [371].

The workup of the bisphenol reaction mixture depends very much on the structure of the products and the purity requirements. Basic purification is not necessary for bisphenols used as stabilizers, whereas bisphenol A for polycondensations must be of high purity. Possible workup procedures are, for example, the simple distillation of volatile components from the reaction mixture, washing out starting materials, or recrystallization from suitable solvents. Distillations of bisphenols are generally not carried out because of their thermal lability.

The mechanism for the formation of bisphenols, in particular that for the formation of bisphenol A and its byproducts, is essentially understood [350].

Bisphenol A. There are many processes for the industrial synthesis of this most important bisphenol [362], [372-376]. Currently, hydrogen chloride or sulfonated cross-linked polystyrenes [372], [377-379] are used as the catalyst which are usually arranged as a fixed bed over which the reaction mixture is passed (Fig. 2). The reaction of phenol with acetone takes place at 50 – 90 °C, the molar ratio phenol – acetone is up to 15 : 1. Bisphenol A crystallizes as an adduct with 1 mol phenol, after separation of the hydrogen chloride by distillation or neutralization. The use of ion exchangers is preferred to that of hydrogen chloride because they are less corrosive. The yield is normally 80 –95 %.

Figure 2. Flowchart of a bisphenol A plant according to [383]

a) Storage tank; b) Reactor; c) Column; d) Crystallizer; e) Separator; f) Melt; g) Desorber; h) Flaking off

To isolate the bisphenol, the whole reaction mixture can be fractionally distilled, whereby bisphenol A itself is distilled over particularly carefully under high vacuum, separated from resinous byproducts, and subsequently recrystallized under pressure at elevated temperature [380]. Crude bisphenol A can also be purified by extracting into hot heptane or mixtures of aromatics [381] or by recrystallization from aromatics [382]. A very high purity product with polyester quality is obtained if the bisphenol A – phenol 1 : 1 adduct is separated, recrystallized from phenol, and the phenol removed by distillation [375], [383]. These processes are mostly carried out continuously [372], [374], [376], [380], [383]. The acetone – phenol mixture produced in the Hock phenol synthesis from cumene hydroperoxide can be used as starting material for bisphenol A synthesis [384].

4.4. Analysis, Testing, Storage

Many bisphenols can be analyzed by gas chromatography. The quality of bisphenols can also be tested by measurement of the solidification point and the color index of solutions (bisphenol A in 30 % methanolic solution: APHA color index ≤ 50).

Bisphenols are usually sold as solids, rarely as liquids; bisphenol A is supplied as white flakes which sometimes have a yellow-brown coloration. It can be stored in this form, but not in the molten stage for an unlimited time in stainless steel containers. The pneumatic conveying of bisphenol A must be performed under nitrogen because of the danger of dust explosions.

4.5. Uses, Economic Aspects

Bisphenol A is the most important bisphenol which is used industrially. Since it is mainly used for the production of high-grade plastics, the demand has increased sharply with industrial development.

In 1976, production of bisphenol A in the United States (producers: Shell, General Electric, Dow, Aristech, Union Carbide) amounted to 168 000 t, and in Western Europe (producers: Bayer, Shell, Rhône-Poulenc, General Electric, Dow) 136 000 t were consumed. In line with the rapid industrial growth of the 1980s, world bisphenol A production capacity rose to 10^6 t, a figure which will presumably be exceeded in 1990. About 50 % of this capacity is located in the United States, over 30 % in Western Europe, and the remainder mostly in Japan. However, due to the current economic decline, the new overcapacity is only gradually being utilized.

Whereas in the mid-1970s ca. 50 % of the bisphenol A was converted to epoxy resins and only 40 % to polycarbonates [346], [385], in 1989 over 50 % was used for polycarbonates and ca. 40 % for epoxy resins. The remainder is used for a wide range of products such as aromatic polyesters with phthalic acid; polysulfones; polyetherketones; unsaturated, hydrolysis-resistant polyesters [386]; antioxidants; phenoxy resins from bisphenol A and epichlorohydrin [387]; and phenolic resins elastified by incorporation of bisphenol A [388]. However, the majority is used for flame retardants, especially tetrabromobisphenol A [389].

Polyester resins can be linked with phenolic resins via 4,4 bis(4-hydroxyphenyl)pentanoic acid (see Table 15, [387]. Bisphenol Z is used in the production of polycarbonate films [390].

Bisphenol Z and bisphenol A substituted with various ortho-alkyl groups counteract coccidiosis in poultry [391] and bisphenols containing nitrogen heterocycles are said to act as laxatives [392].

4.6. Toxicology

Bisphenols are far less toxic than phenol itself. Therefore some of them can even be used as antioxidants in cosmetics and foods.

Bisphenol A has an LD_{50} (mouse) of 4 g/kg, limits the weight gain in rats in feeding experiments, and has a clearly estrogenic effect. The permeation of bisphenol A through the skin is practically negligible compared with phenol. It is, however, reported that bisphenol A leads to minor skin irritation .

5. Hydroxybiphenyls

Hans-Josef Buysch

5.1. Physical Properties

Hydroxybiphenyls are colorless solids with a weak odor (if any). They are only sparingly soluble in water, but most of them dissolve readily in sodium hydroxide to form salts. Polar organic solvents such as alcohols, ethers, esters, and ketones have an outstanding solvent power for hydroxybiphenyls, whereas that of nonpolar solvents such as aromatic and aliphatic hydrocarbons is lower. The para-hydroxybiphenyls are generally less soluble than the *o*-hydroxybiphenyls. The solubilities can be affected considerably by substitution. Thus, e.g., (**22**) is soluble in various organic solvents but insoluble in water and 10 % sodium hydroxide.

Some physical properties are given in Table 16. 2-Hydroxybiphenyl (**18**) has the greatest industrial importance; further physical properties for 2-hydroxybiphenyl are summarized as follows:

Solubility (g/100 g solvent at 25 °C) in	
methanol	800
ethanol	590
acetone	660
white spirit	20
water	0.07
at 100 °C	0.13
10 % NaOH	50
Heat of fusion	91 J/g
Flash point	138 °C
Ignition temperature	520 °C
Vapor pressure (100 °C)	70 Pa

Table 16. Physical properties of some hydroxybiphenyls

Name	CAS registry no.	Structural formula	Molecular formula	M_r	*mp*, °C	*bp*, °C	d_4^{20}
2-Hydroxybiphenyl	[*90-43-7*]	**18**	$C_{12}H_{10}O$	170.1	57	286	1.219
4-Hydroxybiphenyl	[*92-69-3*]	**19**	$C_{12}H_{10}O$	170.1	165	312	
2,2′-Dihydroxybiphenyl	[*1806-29-7*]	**20**	$C_{12}H_{10}O_2$	186.2	109		
4,4′-Dihydroxybiphenyl	[*92-88-6*]	**21**	$C_{12}H_{10}O_2$	186.2	274–275		
3,5,3′,5′-Tetra-*tert*-butyl-4,4′-dihydroxybiphenyl	[*2455-14-3*]	**22**	$C_{28}H_{42}O_2$	410.6	185		

5.2. Chemical Properties

The chemical properties of hydroxybiphenyls are very similar to those of phenol itself. Phenyl substitution has a small but insignificant deactivating effect on the other phenyl nucleus; in the ortho-position it also causes steric hindrance, which is, however, still lower than that of the *tert*-butyl group.

Accordingly, hydroxybiphenyls can undergo reactions at the OH group involving etherification, esterification, and salt formation in the usual way. Because of their bifunctionality, dihydroxybiphenyls, especially 4,4-dihydroxybiphenyl, can be converted into polycondensation products which have achieved a limited industrial importance as liquid crystal polymers.

Substitution at the ring (halogenation, sulfonation, nitration, and alkylation) also takes place as expected. In addition, 4,4′-dihydroxybiphenyls can be oxidized to yield diphenoquinones [394] and 2,2′-dihydroxybiphenyls can undergo ring-closure reactions to form dibenzofurans, carbazoles, and dibenzothiophenes [395].

5.3. Production

2-Hydroxybiphenyl (2-Phenylphenol). The starting material for the synthesis of 2-hydroxybiphenyl (**18**) is cyclohexanone, which is first autocondensed to form 2-cyclohexenylcyclohexanone. This reaction is catalyzed by acidic ion exchangers or by metal salts of higher aliphatic carboxylic acids [396]. 2-Cyclohexenylcyclohexanone is subsequently dehydrogenated to (**16**) in the gas phase with noble metal catalysts on an inert carrier material [396-398].

2-Hydroxybiphenyl is formed as a byproduct in the pressure phenol synthesis from chlorobenzene (⟶ Phenol – Chlorination of Benzene).

4-Hydroxybiphenyl (**19**) is formed alongside (**18**) as a byproduct in the alkaline pressure hydrolysis of chlorobenzene to phenol in 5 – 6 % yield. The mixture consists of 2/3 ortho and 1/3 para isomer which can be separated by fractional distillation.

4-Hydroxybiphenyl can also be produced by sulfonation of biphenyl and alkaline fusion of the *para*-biphenylsulfonic acid [399].

2,2′-Dihydroxybiphenyl (**20**) is obtained by alkaline fusion of biphenylene oxide at ca. 300 °C (sometimes catalyzed by fluorene or carbazole [400], [401]) or by debutylation of 3,3′,5,5′-tetra-*tert*-butyl-2,2′-dihydroxybiphenyl, which itself is produced by the oxidative coupling of 2,4-di-*tert*-butylphenol [402]. 2,2′-Dihydroxy-5,5′-dimethylbiphenyl can be synthesized accordingly.

4,4′-Dihydroxybiphenyl (**21**) can also be synthesized in excellent yields by debutylation of 3,3′,5,5′-tetra-*tert*-butyl-4,4′-dihydroxybiphenyl [403]. Other production processes are the alkaline fusion of 4,4′-biphenyldisulfonic acid, the boil down of benzidinebisdiazonium salts [404], and the decarboxylation of 4,4′-dihydroxybiphenyl-2-carboxylic acid [405]. Symmetrically alkylated 4,4′-dihydroxybiphenyls such as (**22**) or 4,4′-dihydroxy-2,2′,3,3′,5,5′,6,6′-hexamethylbiphenyl are preferably obtained by the oxidative coupling of the corresponding substituted monophenols [403], [406]. Here, diphenoquinones are generally formed in the first step which must be reduced. Phenol itself always gives isomeric mixtures of dihydroxybiphenyls on coupling with various oxidants [407]. These mixtures are also formed by alkaline fusion of 4,4′-dihydroxybiphenylsulfone [408].

5.4. Analysis, Quality Specifications, Storage

The purity of 2-hydroxybiphenyl can be determined by gas chromatography or by titration [409]. The melting point should be 56 – 58 °C.

Commercially 2-hydroxybiphenyl is supplied as virtually colorless and odorless flakes or in the form of the sodium salt (NaOH content < 1.0 %). In the absence of light and moisture it can be stored indefinitely.

5.5. Uses

2-Hydroxybiphenyl shows a broad effectiveness against bacteria, yeasts, and mold, but low toxicity towards warm-blooded organisms [410] and very good biodegradability [411]. Therefore it is increasingly used as a preservative and fungicide and for the production of disinfectants in the leather, paper, glue, textile, plastics, and cosmetics industries. 2-Hydroxybiphenyl and its sodium salt are used for the preservation of citrus fruits in their skins (approval according to EC guideline no. E 321).

2-Hydroxybiphenyl is also used as a dyeing accelerant for dyeing synthetic fibers, e.g., polyethylene terephthalate and cellulose triacetate (Levegal OPS, Bayer).

Sulfonation of 2-hydroxybiphenyl and condensation with formaldehyde yields a dispersion agent that is used in the formulation of plant protection agents in aqueous solution [412].

Trade names for 2-hydroxybiphenyl are:

Preventol O extra (Bayer, content > 99.5 %)
Preventol ON extra (Bayer, sodium salt)
Dowicide 1 (DOW), Dowicide A (DOW, sodium salt)
Cotane (Coalite)

4-Hydroxybiphenyl is an intermediate for the production of varnish resins and nonionogenic emulsifiers (trade names: Emulgator W and Emulvin W, Bayer) which are used in the plant protection, polyurethane, and dyeing sectors.

Other Hydroxybiphenyls. A range of possible applications have been proposed for **20**, **21**, and **22**: e.g., as a fungicide (**20**), an antiseptic for feeds (**20**), (**21**), a toner for xerography

(**20**), starting materials for polyesters, polycarbonates, and powder coatings (**21**). Mixtures of isomers of chlorinated and brominated dihydroxybiphenyls (e.g., chlorinated **20**) are used for flameproofing plastics and have been proposed for combating algae and bacteria. However, dihydroxybiphenyls are actually only used as stabilizers and antioxidants, principally **22**, in oils, rubber, and polyolefins.

5.6. Toxicology

The toxicity of 2-hydroxybiphenyl towards warm-blooded organisms is usually low for a phenolic compound. The LD_{50} for rats is 2700 – 3000 mg per kilogram body weight. Accumulation in rat tissue was not established even after feeding over a period of 2 years with feeds containing 2 % 2-hydroxybiphenyl. Daily doses of 200 mg/kg did not produce any harmful effects even after administration for several weeks. Human skin is neither irritated nor sensitized by application of a 5 % solution in oil [409], [410]. 2-Hydroxybiphenyl is toxic to fish in concentrations > 2 mg/L. However, since it is rapidly and completely degraded in biological sewage treatment plants, fishing grounds are not endangered [411].

[Top of Page]

6. Phenol Ethers

Dorothea Garbe

Phenol ethers are organic compounds of the general formula Ar – O – R, in which Ar represents a substituted or unsubstituted phenyl ring and R is a substituted or unsubstituted aliphatic or aromatic hydrocarbon group.

6.1. Properties

Physical Properties. Most phenol ethers have a pleasant, characteristic smell. Some phenol ethers are important in the flavoring and fragrance industry (⟶ Flavors and Fragrances – Phenols and Phenol Derivatives). The ethers described in this article are those, whose importance lies mainly in other areas. The lower phenol ethers are colorless liquids that are insoluble in water and soluble in organic solvents.

Chemical Properties. The ether linkage in phenol ethers is very stable. The carbon – oxygen bond in completely aromatic phenol ethers such as diphenyl ether is cleaved only under drastic conditions, e.g., with alkalis at high temperature and pressure; in contrast, the aliphatic carbon – oxygen bond in anisole, for example, is split by treatment with strong acids such as hydrogen iodide to form phenol and an alkyl iodide. Sterically hindered methoxy groups can be cleaved selectively with BCl_3. The phenyl ring is susceptible to substitution reactions, including hydroxylation, nitration, halogenation, and sulfonation. Phenol ethers can be alkylated or acylated by Friedel – Crafts reactions. Aromatic – aliphatic ethers, however, can also be cleaved in the presence of Friedel – Crafts catalysts at high temperatures.

6.2. Production

Nearly all phenol ethers can be prepared by the reaction of phenols with alkyl or aryl halides (preferably chlorides) in weakly basic aqueous media:

$$C_6H_5ONa + RCl \rightarrow C_6H_5OR + NaCl$$

For the preparation of phenol ethers with short-chain aliphatic groups, dialkyl sulfates are often employed as alkylating agents:

$$C_6H_5OH + (RO)_2SO_2 \xrightarrow{NaOH} C_6H_5OR + (RO)SO_3Na + H_2O$$

The second alkyl group present in the monoalkyl sulfate can be reacted using higher temperatures. Another method for the preparation of aromatic – aliphatic ethers is the etherification of phenols with aliphatic alcohols in the presence of an acidic ion exchanger [413]. This reaction is performed using excess phenol to suppress formation of the dialkyl ether [414].

6.3. Representative Phenol Ethers

Phenyl methyl ether [100-66-3] (**23**), anisole, C_7H_8O, M_r 108.15, *mp* –37.5 °C, *bp* (101.3 kPa) 155 °C, d_4^{20} 0.9954, is a colorless liquid with a spicy-sweet smell. Anisole can be produced by all

23

the aforementioned methods. It is an important intermediate in the synthesis of organic compounds, for example fragrances and pharmaceuticals. The compound is also used as a solvent and as a heat transfer medium.

Phenyl ethyl ether [103-73-1] (**24**), phenetole, $C_8H_{10}O$, M_r 122.17, *mp* –29.5 °C, *bp* (101.3 kPa) 170 °C, d_4^{20} 0.966, is a colorless liquid which is prepared by etherification of phenol with ethyl chloride or diethyl sulfate. Phenyl ethyl ether is an intermediate in numerous organic syntheses.

24

Diphenyl ether [101-84-8] (**25**), $C_{12}H_{10}O$, M_r 170.21, *mp* 26.8 °C, *bp* (101.3 kPa) 257.9 °C, *bp* (1.34 kPa) 121 °C, d_4^{20} 1.0748, occurs, e.g., in lemon balm oil. The compound forms colorless

25

crystals that possess a geranium-like aroma. Diphenyl ether is formed as a byproduct in the high-pressure hydrolysis of chlorobenzene. Because of its high thermal stability, a eutectic mixture of diphenyl ether and biphenyl is employed as a heat transfer medium. Diphenyl ether is the starting material for organic intermediates and is used as a fragrance component. The compound is also employed as a processing aid in the production of polyesters [415]; several polybromine derivatives of diphenyl ether are used as fire retardants.

2-Phenoxyethanol [122-99-6] (**26**), $C_8H_{10}O_2$, M_r 138.17, *mp* –2 °C, *bp* (101.3 kPa) 237 °C, *bp* (2.4 kPa) 134 – 135 °C, d^{20} 1.0020, is a colorless liquid with a faint rose-like aroma.

26

2-Phenoxy-ethanol is produced by the hydroxyethylation of phenol, for example, in the presence of alkali-metal hydroxides or alkali-metal borohydrides [416]. The compound is known under the trade name Cellosolve as a solvent for cellulose acetate. 2-Phenoxyethanol is a synthetic intermediate in the production of plasticizers, pharmaceuticals, and fragrances. In the perfume industry the compound finds use as a fixing agent.

Phenoxyacetic acid [122-59-8] (**27**), $C_8H_8O_3$, M_r 152.16, *mp* 98 – 99 °C, *bp* (101.3 kPa) 285 °C (decomp.), forms colorless crystals that possess a faint honey-like odor and are soluble in the common organic solvents.

27

Phenoxyacetic acid can be prepared by reaction of phenol with chloroacetic acid in dilute aqueous sodium hydroxide, or by hydrolysis of its methyl ester. The methyl ester is obtained by reaction of phenol and methyl chloroacetate in the gas phase with zinc oxide – aluminum oxide as catalyst [417]. Phenoxyacetic acid is an intermediate for fragrances and dyes and is a starting material for the synthesis of penicillin V.

4-Methylanisole [104-93-8] (**28**), $C_8H_{10}O$, M_r 122.17, *bp* (101.3 kPa) 176.5 °C, d_{25}^{25} 0.9698, is a colorless liquid with a pungent odor, which in dilute solution has a flower-like

fragrance. 4-Methylanisole is a starting material for the preparation of *p*-anisaldehyde.

28

2-Methoxyphenol [90-05-1] (**29**), guaiacol, $C_7H_8O_2$, M_r 124.15, *bp* (101.3 kPa) 205 °C, *bp* (3.2 kPa) 106.5 °C, d_4^{21} 1.128, forms colorless prisms that have a sweet, faint phenol odor. Guaiacol is present in many essential oils and is also found as a flavor compound in many foods. Guaiacol is prepared by monomethylation of catechol using methyl halides or dimethyl sulfate. Monomethylation of catechol can also be accomplished with methanol in the presence of phosphoric acid, phosphates, or an ion exchanger [418]. Guaiacol is an important synthetic intermediate in the flavoring and fragrance industries (e.g., for the synthesis of vanillin), as well as in the pharmaceutical industry.

29

2-Ethoxyphenol [94-71-3] (**30**), $C_8H_{10}O_2$, M_r 138.17, *mp* 29 °C, *bp* (101.3 kPa) 217 °C, *bp* (5.3 kPa) 68 °C, is prepared analogously to guaiacol by monoetherification of catechol. The compound is an intermediate in the synthesis of ethyl vanillin.

30

2-Isopropoxyphenol [4812-20-8] (**31**), $C_9H_{12}O_2$, M_r 152.20, *bp* (101.3 kPa) 217 °C, *bp* (14.7 kPa) 100 – 102 °C, is prepared by monoetherification of catechol with isopropyl halides in the presence of alkali-metal salts and either a phase transfer catalyst [419] or a polyhydroxyalkyl monoether in an autoclave [420]. This compound is the starting material for the synthesis of the pesticide Propoxur (2-isopropoxyphenyl methylcarbamate).

31

Veratrole [91-16-7] (**32**), $C_8H_{10}O_2$, M_r 138.17, *mp* 22.5 °C, *bp* (101.3 kPa) 206 °C, *bp* (1.3 kPa) 90 °C, d_{25}^{25} 1.084, is prepared by methylation of catechol or guaiacol. This compound is an intermediate in the synthesis of alkaloids and pharmaceuticals.

32

1,3-Benzodioxole [274-09-9] (**33**), $C_7H_6O_2$, M_r 122.13, *bp* (101.3 kPa) 172 °C, is a colorless liquid. This compound is prepared by the reaction of catechol and dihalomethanes, for example, by use of concentrated aqueous alkaline solution in the presence of tetraalkylammonium or phosphonium salts [421], sometimes in the presence of alkyl iodides [422]. 1,3-Benzodioxole is an important intermediate in organic synthesis, especially for the preparation of alkaloids.

7. Halogen Derivatives of Phenolic Compounds

Wilfried Paulus

The phenolic derivatives described in this chapter include halogenated alkylphenols, cycloalkylphenols, arylphenols, alkylarylphenols, phenoxyphenols, dihydroxydiphenyl sulfides (thiobisphenols) and halogenated salicylanilides. They all possess antimicrobial properties and are therefore widely used as microbicides. Depending on their chemical and physical properties, the compounds can be used (1) as preservatives for functional fluids, (2) to control slime in process water systems, (3) to protect various materials e.g., textiles, paper, and wood against microbial decay, and (4) as active ingredients in disinfectants (for halogenated phenol derivatives used in disinfectants, see ⟶ Disinfectants). Pentachlorophenol (PCP) is not discussed in this chapter even though it can be widely used as a biocide. The use of PCP as a biocide is rapidly declining because of its ecotoxicity and general toxicity. The production, use, and marketing of PCP and PCP-containing products has been banned in various countries, e.g., in the Federal Republic of Germany from January 1, 1990.

Similarly, 2,4,5- and 2,4,6-trichlorophenol are not included in this chapter although they possess strong microbicidal properties. There is pressure to find suitable substitutes for these compounds because they are the starting materials in the formation of the highly toxic tetrachlorodibenzo-*p*-dioxins.

7.1. Introduction

Phenol (formerly known as carbolic acid) was discovered in 1834. In 1860, the antiseptic properties of phenol were recognized and used for antibacterial treatment of surgical instruments and bandaging material and for treatment of wounds. This was the beginning of the use of chemical methods to kill microbes or to inhibit their growth. At the same time, the toxic and skin-cauterizing properties of phenol itself led to the isolation and syntheses of hundreds of phenol derivatives with the aim of finding less toxic phenol derivatives and more effective compounds which required lower concentrations for use. With the discovery that chemicals could be used to protect materials against microbial attack and decay, phenol derivatives with suitable chemical and physical properties were investigated for such uses. This development, which can now be considered complete, also led to discovery of the correlation between structure and effectiveness and the mechanism of action of phenol derivatives [431].

Phenol derivatives are so-called membrane-active microbicides. Initially, they are reversibly adsorbed on the surface of microbe cells and inhibit metabolic processes. If applied in higher concentrations, the phenol derivatives dissolve fairly quickly and readily in lipids according to their chemical and physical properties and penetrate into the microbe cell. They react with the protoplasma and cell proteins and inhibit enzymes, which leads to destruction of the microbial cell. The applied concentration determines whether the phenol derivatives act microbistatically or microbicidally.

Phenol derivatives show optimal antimicrobial effect in neutral and acid media, i.e., in the undissociated state, since only in this state are they membrane-active and exhibit affinity for the negatively charged surface of the microbial cell wall; the negatively charged phenolate anions are repelled. Therefore, if optimal advantage is to be taken of the antimicrobial power of phenol deravatives during application, their pK_a values must be taken into account. The pK_a values for some important phenolic microbicides are listed in the following:

2-Hydroxybiphenyl	11.6
6-Isopropyl-3-methylphenol	10.6
4-Chloro-3,5-dimethylphenol	9.7
4-Chloro-3-methylphenol	9.6
2,4,6-Trichlorophenol	8.5
4-Chloro-2-(2,4-dichloro)phenoxyphenol	7.9
2,2′-Methylenebis(4-chlorophenol)	
pK_a (1)	8.7
pK_a (2)	12.6

Halogenation of phenol derivatives produces active substances with substantially increased antimicrobial effect. The acidity of the compounds is also more pronounced; the degree of dissociation of halogenated phenol derivatives increases with the number of halogen atoms (see above). The combination of alkylation and halogenation — the latter preferably in

the 4-position — produces phenolic microbicides which have great practical importance as active ingredients in disinfectants and for the preservation of materials. These include 2-benzyl-4-chlorophenol, 4-chloro-3-methylphenol, and 4-chloro-3,5-dimethylphenol. The minimum inhibitory concentrations listed in Table 17 give an indication of the range of effect of halogenated phenol derivatives which have particular practical importance as microbicides.

Table 17. Minimum inhibitory concentration (MIC) of halogenated phenol derivatives in nutrient agar

Test organisms	MIC, mg/L				
	PCMC [a]	PCMX [b]	Chlorophene [c]	Dichlorophene [d]	Fenticlor [e]
Bacillus subtilis	150	75	10	100	
Bacillus punctatum	200	100	10	50	
Escherichia coli	250	200	3500	100	75
Leuconostoc mesenteroides	200	100	10	5	3500
Proteus vulgaris	200	200	100	50	
Pseudomonas aeruginosa	800	1000	5000	>5000	
Staphylococcus aureus	200	100	20	5	35
Desulfovibrio desulfuricans	35	50	50	20	
Candida albicans	200	75	50	50	50
Torula rubra	50	100	50	50	50
Aspergillus niger	100	100	100	100	50
Aureobasidium pullulans	30	50	20	35	<20
Chaetomium globosum	80	50	20	20	75
Cladosporium herbarum	200	100	100	200	35
Coniophora puteana	100	35	5	2	<20
Penicillium citrinum	100	50	75	50	20
Penicillium glaucum	100	35	50	50	10
Polyporus versicolor	5000	75	50	50	35
Trichoderma viride	140	100	100	50	50
Trichophyton pedis	100	50	10	10	10

[a] PCMC = 4-chloro-3-methylphenol.
[b] PCMX = 4-chloro-3,5-dimethylphenol.
[c] Chlorophene = 2-benzyl-4-chlorophenol.
[d] Dichlorophene = 2,2′-methylenebis(4-chlorophenol).
[e] Fenticlor = 2,2′-thiobis(4-chlorophenol).

It is often claimed that phenols, especially chlorinated phenols, show high oral toxicity, are toxic percutaneously, and are in general difficult or impossible to degrade biologically. This disqualification of phenols is a very unreliable generalization and is not verified by the facts. The whole class of phenolic microbicides must not be looked at uniformly and unjustly disqualified, just because some representatives of this class of compounds indeed possess properties such as high ecotoxicity, are persistent, and can contain dioxins. Even some of the halogenated phenol derivatives have toxicological properties and ecological effects which satisfy the standards for microbicides used for preservation of materials and for disinfectants that are set by a civilization with an increased sense of responsibility for the environment. As shown by the curves in Figure 3, there are phenol derivatives including halogenated phenols which can be biodegraded quickly and effectively, and others, e.g., pentachlorophenol which are only biodegraded slowly and only if present in very low concentrations [423]. The biodegradation of phenols does not only occur in biological sewage plants; surface waters also possess a considerable potential to biodegrade phenol derivatives including pentachlorophenol [424].

Figure 3. Biodegradability of various phenol derivatives

a) 2-Hydroxybiphenyl, 100 ppm; b) 4-Chloro-3-methylphenol, 50 ppm; c) Benzylphenol, 20 ppm; d) 2-Benzyl-4-chlorophenol, 50 ppm; e) Dichlorophene, 20 ppm; f) 4-Chloro-3,5-dimethylphenol, 10 ppm; g) Pentachlorophenol, 10 ppm

7.2. Representative Compounds

4-Chloro-3-methylphenol [59-50-7] (**34**), *p*-chloro-*m*-cresol, PCMC, C_7H_7ClO, M_r 142.59, has a density ϱ 1.37 g/cm^3 at 20 °C, a vapor pressure of 8 Pa at 20 °C, of 0.7 kPa at 100 °C, a *mp* of 63 – 65 °C, a *bp* of ca. 239 °C, the flash point is ca. 118 °C, and the ignition temperature ca. 590 °C. Its solubility in water is 4 g/L. 4-Chloro-3-methylphenol is readily soluble in alkali solutions and organic solvents, and has a pK_a of 9.6.

Toxicological Data [431], [432]. LD_{50} (oral, rat) 5129 mg/kg, LD_{50} (dermal, rat) >500 mg/kg (exposure 7 d). PCMC irritates the skin and mucous membranes but is not significantly sensitizing and not mutagenic. LCLo for fish 0.5 mg/L (96 h exposure).

Preparation and Uses. 4-Chloro-3-methylphenol is prepared by chlorination of 3-methylphenol with, e.g., SO_2Cl_2. PCMC is of major importance as a preservative for aqueous functional fluids and as a raw material for disinfectants (⟶ Disinfectants). This is due to its strong and wide-ranging antimicrobial effect combined with favorable chemical and physical properties and good biodegradability [431].

34

2-Benzyl-4-chlorophenol [120-32-1] (**35**), Chlorophene, $C_{13}H_{11}ClO$, M_r 218.69, has a density ϱ 1.22 g/cm^3 at 20 °C, a vapor pressure of 10 Pa at 100 °C, a *mp* of 48 – 49 °C, and a *bp* (1.5 kPa) of 190 – 196 °C. Its flash point is ca. 188 °C, and the ignition temperature ca. 490 °C. 2-Benzyl-4-chlorophenol has a solubility in water of 0.4 g/L at 20 °C. It is readily soluble in alkali solutions and organic solvents and has a pK_a of 11.0.

Toxicological Data. LD_{50} (oral, rat) > 5000 mg/kg, LD_{50} (dermal, rat) > 2500 mg/kg, LC_{50} (inhaled for 4 h, rat) 2.5 mg/L. Chlorophene strongly irritates the skin and mucous membranes but is not toxic percutaneously and is neither mutagenic nor teratogenic. Its LCLo for *Leuciscus idus* is 0.5 mg/L (48 h exposure). Organisms in activated sludge tolerate 10 – 50 mg/L Chlorophene and are able to degrade it [431], [432].

Preparation and Uses. Chlorophene can be prepared by reaction of 2-benzylphenol with SO_2Cl_2 at 100 °C. It is used as an active agent in disinfectants (⟶ Disinfectants).

35

4-Chloro-2-cyclopentylphenol [13347-42-7] (**36**), $C_{11}H_{13}ClO$, M_r 196.68, *mp* 23.7 °C, *bp* 303 °C, has a solubility in water of 0.24 g/L at 20 °C, and is readily soluble in organic solvents.

Toxicological Data. LD_{50} (oral, rat) 2460 mg/kg, LD_{50} (oral, rabbit) 420 mg/kg, LD_{50} (dermal, rabbit) 850 mg/kg. 4-Chloro-2-cyclopentylphenol strongly irritates the skin and mucous membranes but is not sensitizing.

Preparation. 4-Chloro-2-cyclopentylphenol is prepared by shaking 4-chlorophenol and cyclopentene in concentrated sulfuric acid; 2,6-dicyclopentyl-4-chlorophenol (*bp* 235 – 240 °C at 1.8 kPa) is produced as a byproduct. 4-Chloro-2-cyclopentylphenol is no longer used as a microbicide in disinfectants because of its toxicity.

36

5-Chloro-2-hydroxybiphenyl [1331-46-0] (**37**), monochloro-*o*-phenylphenol, MCOPP, $C_{12}H_9ClO$, M_r 204.66, *mp* 36 – 37 °C, *bp* (1.5 kPa) 178 °C, is very sparingly soluble in water and readily soluble in organic solvents.

Toxicological Data. LD_{50} (oral, rat) 3500 mg/kg. 5-Chloro-2-hydroxybiphenyl is toxic percutaneously, irritates the skin and mucous membranes, and can cause photoallergic contact dermatitis. 5-Chloro-2-hydroxybiphenyl is no longer used as a microbicide in disinfectants because of these properties.

Preparation. 5-Chloro-2-hydroxybiphenyl is obtained along with 2-chloro-6-hydroxybiphenyl when chlorine is introduced into 2-hydroxybiphenyl.

37

4-Chloro-3,5-dimethylphenol [88-04-0] (**38**), *p*-chloro-*m*-xylenol, PCMX, C_8H_9ClO, M_r 156.61, *mp* 114 – 116 °C, *bp* 246 °C, has a vapor pressure of 0.3 kPa at 100 °C, its solubility in water is 0.33 g/L at 20 °C. 4-Chloro-3,5-dimethylphenol is soluble in alkali solutions and organic solvents, and has a pK_a of 9.7.

Toxicological Data. LD_{50} (oral, rat) 3830 mg/kg. PCMX mildly irritates the skin and mucous membranes, has a low sensitization potential, is not mutagenic in the Ames test, and is not teratogenic in rats; the LCLo for *Leuciscus idus* is 1 mg/L. Organisms in activated sludge tolerate 15 mg/L PCMX and slowly degrade the substance [431], [432].

Preparation and Uses. 4-Chloro-3,5-dimethylphenol is prepared by reaction of 3,5-dimethylphenol with chlorine at 25 – 30 °C or with SO_2Cl_2 starting at 30 – 40 °C [425]. It is used as a raw material for disinfectants (⟶ Disinfectants), as an active component in deodorants, soaps, skin preparations for dermatological disorders, and antiseptics, and as a preservative for aqueous functional fluids.

38

4-Chloro-6-isopropyl-3-methylphenol [89-68-9] (**39**), 4-chlorothymol, $C_{10}H_{13}ClO$, M_r 184.67, *mp* 64 °C, *bp* 259 – 263 °C, has a solubility in water of 0.3 g/L at 20 °C, is soluble in alkali solutions and readily soluble in organic solvents.

Toxicological Data. LD_{50} (oral, mouse) 2460 mg/kg.

Preparation and Uses. 4-Chloro-6-isopropyl-3-methylphenol is prepared by reaction of equimolar amounts of propene and 4-chloro-3-methylphenol in the presence of bleaching clay under pressure at 140 – 160 °C or by chlorination of thymol with SO_2Cl_2 in chloroform. On account of its microbicidal properties [426], chlorothymol is of importance as a raw material for disinfectants [427] (⟶ Disinfectants).

39

4-Benzyl-2-chloro-6-methylphenol [65053-91-0] (**40**), $C_{14}H_{13}ClO$, M_r 232.72, has a *bp* (27 Pa) of 128 – 129 °C, and an n_D^{20} of 1.5944.

Toxicological Data. LD_{50} (oral, mouse) 1700 mg/kg, LD_{50} (subcutaneous, mouse) 1000 mg/kg, LD_{50} (intravenous, mouse) 96 mg/kg [428].

Preparation. 4-Benzyl-2-chloro-6-methylphenol is prepared from 2-chloro-6-methylphenol (or the forerunnings formed in the production of 4-chloro-2-methylphenol by chlorination of 2-methylphenol) by reaction with benzyl chloride in the presence of anhydrous zinc chloride starting at 100 °C and reaching completion after 5 h at 150 – 155 °C [428].

Uses. The substance shows a strong antimicrobial effect especially towards bacteria and fungi, and in particular dermatophytes. The microbicide is used mostly for epidermal applications, e.g., in pharmaceuticals, cosmetics, and soaps because it is tolerated well by skin and has a low skin-sensitization potential (⟶ Disinfectants).

40

4-Bromo-2,6-dimethylphenol [2374-05-2] (**41**), 4-bromo-2,6-xylenol, C_8H_9BrO, M_r 201.08, has a *mp* of 80 – 81 °C.

Toxicological Data. LD_{50} (i.p., mouse) 650 mg/kg.

Preparation and Uses. 4-Bromo-2,6-dimethylphenol is prepared by bromination of 2,6-dimethylphenol in glacial acetic acid at 15 °C and used as a microbicide in disinfectants (⟶ Disinfectants).

41

2,4-Dichloro-3,5-dimethylphenol [133-53-9] (**42**), dichloro-*m*-xylenol, DCMX, $C_8H_8Cl_2O$, M_r 191.06, *mp* 95 – 96 °C (sublimation), *bp* 250 °C, flash point 134 °C, has a solubility in water of 0.2 g/L at 20 °C, is soluble in alkali solutions, and readily soluble in organic solvents.

Toxicological Data. LD_{50} (oral, rat) is 2810 – 4120 mg/kg.

Preparation and Uses. DCMX is obtained by reaction of 4-chloro-3,5-dimethylphenol with *N*-chloroacetamide in glacial acetic acid with concentrated HCl. It is used as a preservative in aqueous functional fluids and as a microbicide in disinfectants, but in comparison with PCMX (**38**) is of lesser importance because it has a more intense smell and is less soluble in water.

42

Tetrabromo-2-methylphenol [576-55-6] (**43**), 3,4,5,6-tetrabromo-*o*-cresol, $C_7H_4Br_4O$, M_r 423.75, *mp* 205 – 208 °C, is practically insoluble in water. The solubility (g/L) in various solvents is as follows: ethanol 85, isopropanol 80, ethylene glycol 9, propylene glycol 8, vaseline oil 4. Tetrabromo-2-methylphenol discolors in light and in contact with traces of iron.

Toxicological Data. Tetrabromo-2-methylphenol has an LD_{50} (oral, rat) > 6400 mg/kg and is well tolerated by skin and mucous membranes.

Preparation and Uses. Tetrabromo-2-methylphenol is obtained by reaction of *o*-cresol with bromine in tetrachloromethane in the presence of aluminum and iron powder. It is used as a preservative for cosmetics, as an active component in deodorants and disinfectants (⟶ Disinfectants), and as an active agent for antimycotic finishing of textile materials; it is, however, of minor importance [432].

43

5-Chloro-2-(2,4-dichlorophenoxy)phenol [3380-34-5] (**44**), 2,4,4′-trichloro-2′-hydroxydiphenylether, Triclosan, $C_{12}H_7Cl_3O_2$, M_r 289.55, *mp* 60 – 61 °C, decomposes at 280 – 290 °C. The vapor pressure is 2.6 Pa at 100 °C. The solubility (g/L) in various solvents is as follows: water 0.01 at 20 °C, 0.039 at 50 °C, in 0.1 mol/L NaOH 23; it is readily soluble in organic solvents. Triclosan has a pK_a of 7.9, is unstable in light, and discolors in contact with traces of heavy metals. Under certain conditions such as higher alkalinity and heat, conversion to chlorinated dibenzo-*p*-dioxines can occur.

Toxicological Data [432]. LD_{50} (oral, rat or dog) > 5000 mg/kg, LD_{50} (intravenous, rat) 29 mg/kg, LD_{50} (intraperitoneal, rat) 198 mg/kg. Triclosan is neither mutagenic nor teratogenic, is tolerated well by the skin, and has shown no evidence of sensitization potential, LCLo for fish is ca. 0.6 mg/L (exposure 48 h). Activated sludge organisms tolerate up to 10 mg/L Triclosan and degrade the substance slowly.

Preparation and Uses. Triclosan is produced by treatment of 2,4,4′-trichloro-2′-methoxydiphenyl ether with $AlCl_3$ in benzene under reflux. It is highly active against staphylococci and is used as an active agent in deodorants and antiseptic soaps (⟶ Disinfectants).

44

2,2′-Methylenebis(4-chlorophenol) [97-23-4] (**45**), Dichlorophene, $C_{13}H_{10}Cl_2O_2$, M_r 269.14, *mp* 176 °C, has a density ϱ 1.5 g/cm^3 at 20 °C, a vapor pressure < 1 Pa at 100 °C, and is not steam-volatile. The solubility (g/L) in different solvents is as follows: water 0.07 at 20 °C, 0.2 at 50 °C; 10 % NaOH 500, butanol 400; toluene 12. Dichlorophene has a pK_a (1) of 8.7 and pK_a (2) of 12.6.

Toxicological Data [431], [432]. LD_{50} (oral, rat) 3300 mg/ kg. Dichlorophene does not irritate the skin, mildly irritates the mucous membranes, and skin sensitization is not significant. Dichlorophene is neither mutagenic nor teratogenic. LCLo for *Leuciscus idus* 0.5 mg/L (72 h exposure); data on biodegradability are given in Figure 3.

Preparation and Uses. Dichlorophene is produced by reaction of 4-chlorophenol with 0.5 M aqueous formaldehyde solution with the addition of sulfuric acid at 50 – 65 °C. On account of its bactericidal and fungicidal properties, the pure nearly odorless compound can be used in deodorants and antiseptic soaps, for antimicrobial finishing of textiles and paper, and as a preservative for metalworking lubricants.

45

4,4′-Methylenebis(2,6-dichlorophenol) [3933-88-8] (**46**), $C_{13}H_8Cl_4O_2$, M_r 338.04, *mp* 184 –185 °C, is produced by introducing chlorine into a solution of 4,4′-methylenebis(2-chlorophenol) in glacial acetic acid at room temperature or by treating 2,6-dichlorophenol with formalin in concentrated sulfuric acid at –10 °C. It has antimicrobial properties, but because of its high toxicity it no longer has practical importance as a microbicide.

46

2,2′-Methylenebis(3,4,6-trichlorophenol) [70-30-4] (**47**), Hexachlorophene, $C_{13}H_6Cl_6O_2$, M_r 406.92, has an *mp* of 164 – 165 °C; its solubility (g/L) in various solvents is as follows: acetone 1010, ethanol 500, toluene 56. Hexachlorophene is soluble in alkalis but practically insoluble in water. Its pK_a values are 5.4 and 10.9.

Toxicological Data [431], [432]. LD_{50} (oral, rat) 59 mg/kg, LD_{50} (oral, mouse) 80 mg/kg. Hexachlorophene is neither mutagenic nor teratogenic; it is however, neurotoxic, irritates the skin and mucous membranes, and is absorbed through the skin.

Preparation and Uses. Hexachlorophene is formed by reaction of 2,4,5-trichlorophenol with paraformaldehyde in fuming sulfuric acid (20 % SO_3) at 65 – 135 °C. Hexachlorophene is a strong bacteriostat which also has a microbicidal effect at high concentrations. The use of Hexachlorophene as an antimicrobial agent in cosmetics, medicinal soaps, detergent solutions, and textiles has, however, been discontinued because of its toxicity. For details on the correlation between chemical structure and biological activity of chlorinated methylenebisphenols and their physical, chemical, and pharmacological properties, see [429].

47

2,2′-Methylenebis(6-bromo-4-chlorophenol) [15435-29-7] (**48**), bromochlorophene, $C_{13}H_8Br_2Cl_2O_2$, M_r 426.95, *mp* 188 – 191 °C, its solubility (g/L) in different solvents is as follows: water < 0.01, 95 % ethanol 0.5, propanol 0.7, isopropanol 0.4, 1.2-propylene glycol 2.5, paraffin oil 0.05.

Toxicological Data [432]. LD_{50} (oral, rat) 3700 mg/kg, LD_{50} (oral, mouse) 1550 mg/kg, LD_{50} (dermal, rat) > 10 000 mg/kg. Bromochlorophene does not irritate the skin and there is no evidence of sensitization.

Preparation and Uses. Bromochlorophene is produced by bromination of 2,2′-methylenebis(4-chlorophenol) in glacial acetic acid in the cold. It is used as a microbicide in cosmetics, e.g., deodorants, mouthwashes, and toothpastes.

48

2,2′-Thiobis(4-chlorophenol) [97-24-5] (**49**), Fenticlor, $C_{12}H_8Cl_2O_2S$, M_r 287.18, *mp* 174 °C, has a solubility in water of 30 mg/L and is readily soluble in alkalis and organic solvents.

Toxicological Data. LD_{50} (oral, rat) 3250 mg/kg; photosensitization of the skin is possible.

Preparation and Uses. Fenticlor is produced (1) by the reaction of 4-chlorophenol with sulfur dichloride in the presence of $AlCl_3$ or (2) by chlorination of 2,2′-thiobisphenol with chlorine in glacial acetic acid or with SO_2Cl_2 in dichlorobenzene. It shows a tendency to discoloration. Fenticlor has a broad range of antimicrobial action; it is, e.g., effective against bacteria, fungi, yeasts, and algae. Fenticlor is therefore used as a preservative for aqueous functional fluids and to control algae and slime in process water circulation systems [431].

49

2,2′-Thiobis(4,6-dichlorophenol) [97-18-7] (**50**), Bithionol, $C_{12}H_6Cl_4O_2S$, M_r 356.07, *mp* 188 °C, is virtually insoluble in water, readily soluble in ethanol, diethyl ether, acetone, glacial acetic acid, and dilute alkalis.

Toxicological Data. LD_{50} (oral, rat) 1430 mg/kg, LD_{50} (oral, mouse) 2100 mg/kg.

Preparation and Uses. Bithionol is prepared by reaction of 2,4-dichlorophenol with sulfur dichloride and $AlCl_3$ in carbon disulfide or tetrachloromethane. It is used as a microbicide to protect aqueous functional fluids from biodeterioration and to control algae and slime formation in process water systems [431].

50

2,2′-Thiobis(3,4,6-trichlorophenol) [3161-14-6] (**51**), $C_{12}H_4Cl_6O_2S$, M_r 424.97, *mp* 157 – 159 °C, is practically insoluble in water, readily soluble in ethanol, diethyl ether, acetone, and glacial acetic acid. It is prepared by reaction of 2,4,5-trichlorophenol with SCl_2 and $AlCl_3$ in 1,2-dichloroethane at 45 °C. Its use as a microbicide is declining because of its toxicity.

51

3,3′-Thiobis(2,4,6-trichlorophenol) [104294-11-3] (**52**), $C_{12}H_4Cl_6O_2S$, M_r 424.97, *mp* 285 °C, is prepared by reaction of 2,4,6-trichlorophenol with SCl_2 in the presence of $AlCl_3$ in carbon disulfide or tetrachloromethane. Its use as a microbicide is declining.

52

5,2′-Dichlorosalicylanilide [6626-92-2] (**53**), $C_{13}H_9Cl_2NO_2$, M_r 282.14, *mp* 188 °C, is produced by heating equimolar quantities of 3-chlorosalicylic acid and 2-chloroaniline in the presence of PCl_3 in chlorobenzene or toluene.

53

5,3′,4′-Trichlorosalicylanilide [642-84-2] (**54**), Anobial, $C_{13}H_8Cl_3NO_2$, M_r 316.59, *mp* 244 –246 °C, is virtually insoluble in water, soluble in acetone and methanol. It is produced by reaction of 3-chlorosalicylic acid and 3,4-dichloroaniline with PCl_3 in boiling toluene. It is more effective as a microbicide than DBS (**55**), but its use as a microbicide [430] is declining.

54

4,3′,4′-Trichlorosalicylanilide [58622-66-5] (**54a**) $C_{13}H_8Cl_3NO_2$, M_r 316.59, *mp* 221 –

222 °C, is soluble in acetone and methanol and is light-sensitive. It is produced by reaction of 4-chlorosalicylic acid and 3,4-dichloroaniline with $AlCl_3$ and PCl_3 in nitrobenzene. It was formerly used a microbistat in deodorants and soaps [430].

54a

5,4′-Dibromosalicylanilide [87-12-7] (**55**), DBS, Disanyl, $C_{13}H_9Br_2NO_2$, M_r 371.21, *mp* 238 – 245 °C, is very sparingly soluble in water, sparingly soluble in ethanol, and soluble in acetone and dimethylformamide. Its LD_{50} (oral, mouse) is 1700 mg/kg; photosensitization of the skin is possible. 5,4′-Dibromosalicyclanilide is produced from salicylanilide and bromine in acetic acid. DBS has broad antimicrobial activity [430] but its use as a microbicide in, e.g., paper and plastics is declining.

55

3,5,4′-Tribromosalicylanilide [87-10-5] (**56**), TBS, Trisanyl, $C_{13}H_8Br_3NO_2$, M_r 449.96, *mp* 227 – 228 °C, is practically insoluble in water, soluble in hot acetone, and readily soluble in dimethylformamide. Its LD_{50} (oral, rat) is 570 mg/kg; photosensitization of the skin is possible. 3,5,4′-Tribromosalicylanilide is produced by direct bromination of salicylanilide in aqueous acetic acid at 50 – 55 °C or in water containing an emulsifier at 50 – 65 °C. Its use as a microbicide for the protection of materials is declining [430], [432].

1. Introduction

History. The first synthetic resins and plastics were produced by polycondensation of phenol with aldehydes. In 1872 VON BAYER first reported the reaction between phenol and aldehydes. The resins formed were, however, not of industrial and certainly not of scientific interest. The phenol resin condensation was used industrially in 1902 by BLUMER for the production of novolacs, which served as a substitute for shellac.

In 1909 BAEKELAND made the first plastics. He carried out the polycondensation of phenol and formaldehyde to form cross-linked thermosets over several steps.

Besides the production of plastics, phenolic resins were sought as a replacement for natural resins, which were then used on a large scale for oil varnishes. In 1910 oil-soluble modified phenolic resins were produced by BEHRENDS by polycondensation of phenols, formaldehyde, and rosin.

Between 1928 and 1931 phenolic resins gained increased importance through the treatment of resols with fatty oils to give air-drying varnishes. The main problem, an inadequate compatibility of phenolic resins with other varnish raw materials, was solved by using alkylphenols or by etherification of the hydroxymethyl groups of resols with monohydric alcohols.

These varnish applications and the use of phenolic resins as thermosets and electrical insulating materials were the main application areas. However, other polycondensates and, above all, polymers increasingly limited the market for phenolic resins from the mid 1930s onwards. Theoretical work on the constitution and mechanism of formation of phenolic resins was being carried out at that time by VON EULER, HULTZSCH, MEGSON, ZIEGLER, and others, which led to the development of new application areas for phenolic resins, i.e., as adhesives, printing-ink binders, waterborne paints, temperature-resistant binders, and laminated plastics.

The industrial development of phenolic resins is still continuing despite the long history. Their importance is likely to remain considerable because the raw materials can be obtained at reasonable cost from both petroleum and coal. Phenolic resins can be used as raw materials for synthetic fibers and in photoresists for the production of microchips which characterizes the continuing relevance of this group of resins [7].

Classification. Phenolic resins are polycondensation products of phenols and aldehydes, in particular phenol and formaldehyde. DIN 16 916 (ISO 10 082) attempts to define the relevant terms and properties.

The ring hydrogens in the *para*- and both *ortho*-positions relative to the hydroxyl group can react with formaldehyde and thus cross-link to form a three-dimensional network. If at least one of these three positions bears a substituent other than hydrogen, cross-linking is no longer possible and comparatively low molecular mass compounds are formed as the end products of the polycondensation.

Phenolic resins are classified as novolacs and resols. In *resols* the polycondensation is base-catalyzed and has been stopped deliberately before completion. Characteristic functional groups of this class of resins are the hydroxymethyl group and the dimethylene ether bridge. Both are reactive groups. During processing the polycondensation can be restarted by heating and/or addition of catalysts i.e., resols are self-cross-linking. In the case of *novolacs* the polycondensation is brought to completion. The molecular growth of these thermoplastic synthetic resins is limited by addition of a substoichiometric amount of the aldehyde component. Novolacs are phenols that are linked by alkylidene (usually methine) bridges, without functional groups (apart from the phenolic hydroxyl groups), and cannot cure on their own. However, novolacs can be cross-linked by addition of curing agents, such as formaldehyde or hexamethylenetetramine, and give end products similar to resols.

The classification of phenolic resins into novolacs and resols is only strictly valid if phenols which are trifunctional towards formaldehyde are used as starting material, because resols from bifunctional phenols cannot cross-link by themselves. Nevertheless, the polycondensates from substituted phenols are differentiated according to their characteristic groups as *alkylphenol novolacs* (alkylidene bridge) or *alkylphenol resols* (hydroxymethyl group, dimethylene ether bridge).

The third large group are *phenolic resins modified by natural resins*. Besides phenolic hydroxyl groups, they contain double bonds, ester links, and carboxyl groups.

Novolacs. The first step in phenolic resin polycondensation is always the electrophilic attack of a carbonyl compound (generally formaldehyde) on the *para*- and/or *ortho*-positions of a phenol molecule (acid catalysis, Eq. 1) or a phenolate anion (base catalysis, Eq. 2).

Since hydroxymethyl-substituted phenols are more reactive than phenol itself, the hydroxymethylation continues. The hydroxymethyl compounds formed are unstable in acidic medium and are rapidly converted into compounds linked by methylene bridges (Eq. 3). This reaction also occurs in both the *ortho*- and *para*-positions. In basic media hydroxymethyl groups can be stable. At higher temperatures, however, they react with the formation of methylene bridges according to Equation (3). To hinder polyalkylation by cross-linking which would make further processing more difficult or impossible, less than one mole of formaldehyde must be added per mole of phenol.

Novolacs are sometimes used as chemically unmodified synthetic resins. Their main application is based, however, on their capability to undergo cross-linking with hexamethylenetetramine. The reaction occurs at ca. 150 °C according to Equation (4) [8].

Resols. In a strongly acidic medium, hydroxymethyl groups are rapidly converted into methylene bridges. Therefore, the synthesis of resols can only be catalyzed by bases or salts of weak acids or bases. In analogy to the novolacs, the hydroxymethyl groups are formed in the *ortho*- or *para*-positions (Eq. 2). At temperatures above ca. 40 °C the hydroxymethyl groups can react to form dimethylene ether bridges with elimination of water, according to Equation (5). No catalyst is needed for this reaction. The dimethylene ether bridges formed are more stable in the *ortho*- than in the *para*-position. They can be converted into methylene bridges with elimination of formaldehyde (Eq. 6). The formaldehyde liberated is then available for the formation of new hydroxymethyl groups, if a suitable catalyst is present.

The hydroxymethyl groups of resols can also condense directly with other phenol molecules according to Equation (3). In resols therefore, three different types of formaldehyde-derived moieties occur: (1) relatively stable methylene bridges (the only type of linkage in novolacs), (2) hydroxymethyl groups, which are both capable of condensation reactions, and (3) dimethylene ether bridges.

The structure of resols depends not only on the choice of raw materials and their molar ratios, but also on the temperature of formation, concentration of raw materials, presence or absence of solvents, type of catalyst, and catalyst concentration. These parameters determine the structure to a much greater extent than in the case of novolacs.

The catalyst-containing synthetic resins formed are ready to be used industrially. However, the catalyst can also be removed, either before application or during production, because no catalyst is required for the conversion of hydroxymethyl groups into dimethylene ether bridges, a rise in temperature being sufficient.

To affect compatibility (i.e., miscibility) properties the hydrophilic character of resols can be lowered by etherification of the hydroxymethyl group with alcohols according to Equation (7).

Modified Phenolic Resins. Rosin, a natural resin (→Resins, Natural), contains abietic acid and its double bond isomers as main components. Resols react with the unsaturated centers of these resin acids to form polycarboxylic acids with methylene bridges [9].

These condensation products from rosin and phenol – formaldehyde resin are known as albertol acids. They can be converted by esterification with polyols, or by salt formation, into higher molecular mass products which are readily soluble in nonpolar solvents but can release the solvent rapidly.

Albertol acids are also obtained by direct condensation of rosin, phenols, and formaldehyde.

Resols also undergo analogous reactions with other natural or synthetic unsaturated compounds such as fatty oils, rubbers, and polymer oils. A limited increase in the molecular mass or cross-linking can thus be achieved. Whether a particular reaction can be carried out successfully depends on the ratio of the rates of auto-condensation of the starting materials to co-condensation with the other reaction partners, but particularly on their mutual compati-

bility. Phenolic resins are therefore often classified as "water-soluble", "alcohol-soluble", "oil-soluble" etc.

Compatibility of resols with other components can be produced in many ways, e.g., (1) by using ring-alkylated phenols as the raw materials; (2) by etherification of the hydroxymethyl groups with alcohols; (3) by co-condensation of the resol with natural resins; or by a combination of these measures.

2. Physical Properties

Phenolic resins are yellow to brown in color, and the coloration can be very intense. Pale phenolic resins become colored immediately after production during storage or processing. The coloration is less intense only in the case of phenolic resins from *para*-alkyl-substituted phenols. Characteristic UV absorption maxima lie at 254 nm and 280 nm. The IR spectra of phenolic resins are described in [10].

Phenolic resins which are not cross-linked are commercially available as solids or solutions. For particular applications, e.g., in thermosets, the polycondensation can be driven so far that the resins are no longer soluble but can only be swelled by organic solvents. The *softening point* of solid resins can be determined by the capillary melting point according to DIN 53 244, by the ring and ball method, or similar procedures. These temperatures are not melting points in the thermodynamic sense. They characterize a lowering of viscosity caused by a rise in temperature, as a result of which previously crushed resin particles can be observed to coalesce or another change in form occurs.

The *miscibility* with solvents, usually described as "solubility," depends on the structure of the resin ranging from solubility in water to that in naphtha. Resins often have limited miscibility with certain solvents.

The *viscosity* of phenolic resins or their solutions is measured at high concentrations, e.g., in 30 – 80 % solution. Estimation of the degree of condensation from the viscosity is only possible for the same type of resin, because the molecular structure, in particular the presence of hydroxymethyl groups and dimethylene ether bridges, has a great effect on the viscosity. Usually, the results obtained do not depend on the type of viscometer used. Soluble phenolic resins have a broad *molecular mass distribution*: determination (usually by gel permeation chromatography) gives values of more than 50 000 depending on the type of phenol monomer.

Cross-linked phenolic resins are hard substances which only have a small fracture strain and cannot be melted. Decomposition reactions begin at 120 – 250 °C, depending on the molecular structure. There are, however, also types of phenolic resin (phenolic ether resins) which are stable for some time up to 300 °C.

Phenolic resins can be plasticized. Their compatibility with plasticizers can be adjusted by introduction of hydrophilic or hydrophobic groups.

3. Raw Materials

3.1. Phenols

Phenol (→ Phenol). Unsubstituted phenol is the most important of this group. Phenol produced from tar has a greater tendency towards coloration than synthetic phenol. This is, however, not important because phenolic resins tend to darken during production, storage, and use.

Cresols (→ Cresols and Xylenols). Resins produced from cresols are more compatibile to hydrophobic substances than those produced from phenol. Cresols are therefore important principally for the production of varnish resins. The cresol fractions obtained in tar distillation are mixtures of isomers which contain all three cresol isomers and usually also 2,6-dimethylphenol. For the application of these fractions, their content of *meta*-cresol, which is the most reactive component, is particularly important. As only the *m*-position is substituted, *meta*-cresol is trifunctional towards formaldehyde. Of the pure isomers, *ortho*- and *para*-cresols are the usual raw materials for special applications.

para-Alkylphenols (→ Phenol Derivatives). *para*-Alkylphenols are bifunctional towards formaldehyde, i.e., resols produced from *para*-alkylphenols cannot cross-link directly on heating. If a mixed condensation of different phenols with formaldehyde is carried out, their different reaction rates towards formaldehyde must be taken into account. 4-*tert*-Butylphenol (*mp*

99 °C), 4-isooctylphenol (*mp* 72 – 74 °C), 4-hydroxybiphenyl (*mp* 167 °C), and 4-nonylphenol (liquid at room temperature) are mainly used. Other alkylphenols such as isopentylphenol, cyclohexylphenol, dodecylphenol, and cashew oil are also sometimes used. The latter mainly contains phenols with C_{14}-alkenyl substitutents in the *meta*-position.

[*2,2-bis(4-Hydroxyphenyl)propane*] (diphenylolpropane, bisphenol A, Dian, *mp* 155 – 156 °C) is tetrafunctional towards formaldehyde. Polycondensation of bisphenol A and formaldehyde gives relatively pale resins.

Resorcinol (1,3-dihydroxybenzene, *mp* 117 °C) reacts particularly rapidly with formaldehyde and gives resins which can be cross-linked even in an alkaline medium at room temperature.

Other phenol derivatives which can be used as starting materials are, for example, phenol ethers, phenols containing carboxyl groups, and phenoxyacetic acid.

3.2. Aldehydes

Formaldehyde. The most important aldehyde for the production of phenolic resins is formaldehyde (Formaldehyde), which is used as an aqueous solution at concentrations between 30 and 60 %. Besides formaldehyde, the aqueous solutions contain formic acid (oxidation product of formaldehyde) and methanol. Methanol is added to inhibit formation of higher molecular mass polyoxymethylenes, which would precipitate from the aqueous solution. Methanol can intervene in the polycondensation reaction between phenol and formaldehyde by the formation of ethers, acetals, and hemiacetals and promotion of side reactions. Thus, knowledge of the methanol concentration (which should be as low as possible) is important for carrying out polycondensation reactions. Formaldehyde solutions can also be stabilized by certain amines. The methanol concentration can then be kept low.

Paraformaldehyde is a polyoxymethylene with a relatively low molecular mass. Paraformaldehyde depolymerizes in the reaction mixture. The quantity of formaldehyde liberated per unit time increases with decreasing molecular mass of the paraformaldehyde used as starting material. Since phenolic resin condensations can often take place very vigorously, it is important to assess the reactivity of the paraformaldehyde correctly.

Higher aldehydes are less important. In the presence of basic catalysts they preferably undergo side reactions and can therefore generally only be reacted with phenol in an acidic medium. Besides butyraldehyde, benzaldehyde, salicylaldehyde, acrolein, and crotonaldehyde, acetaldehyde and glyoxal are also important. Glyoxal is tetrafunctional towards phenol and gives novolacs with a low content of low molecular mass condensation products.

Hexamethylenetetramine forms adducts with phenols and novolacs very easily, which cross-link on heating. Hexamethylenetetramine is particularly important in the production of thermosetting materials.

3.3. Catalysts

The catalytic action of *acids* on the condensation to produce novolacs is essentially a function of the hydrogen ion concentration. The nature of the anion is less important but must be taken into account because of possible side reactions (sulfonation, ester formation). Besides mineral acids, oxalic acid is often used. It decomposes on heating above 180 °C and thus allows the production of catalyst-free novolacs.

Bases or *salts of weak acids and bases* are suitable as catalysts for resols and novolacs. Catalyst cations are particularly important: whereas alkali hydroxides catalyze the reaction of phenol with formaldehyde in both the *ortho*- and *para*-positions, alkaline-earth metal hydroxides particularly favor formation of *ortho*-products.

Ammonia, amines and hexamethylenetetramine have a catalytic effect. They can be incorporated into the resin by the Mannich reaction.

4. Production

The production of phenolic resins can involve several separate stages. The substitution and condensation reactions between phenols and aldehydes can be carried out separately in terms of both time and location if required, and also

with various catalysts. In addition, hydroxymethyl groups or phenolic hydroxyl groups can be etherified and reactions with unsaturated compounds can be carried out. Resins are frequently worked up by distillation to give concentrated solutions or solid resins. Examples relating to production can be found in [11] and [12].

Corresponding to the great variety of phenolic resins, they are produced over a very broad temperature range which extends from 20 °C in the case of hydroxymethylphenols to more than 280 °C for phenolic resins modified with natural resins. The reactions can be carried out in aqueous solution, organic solvents, or in melts. The reaction is sometimes carried out under pressure to avoid sublimation of, for example, paraformaldehyde or to increase the temperature and thus the reaction rate. Distillations are often performed under vacuum. The phenolic resin plant shown in Figure 1 can be used for all steps in batchwise production. Subsitution and condensation reactions between phenol and formaldehyde are strongly exothermic (the heat of reaction for the formation of methylene bridges in novolacs is −98.7 kJ/mol [11]) and can proceed very fast and vigorously. Therefore, the access to the condensers and overhead and outlet pipes must be kept very wide and the cooling capacity must be designed for rapid condensation and removal of the condensate. To achieve safe industrial production, phenol is always charged to the reactor first and formaldehyde is then added, not vice versa. Because of the low MAK and TLV values (phenol MAK and TWA =5 ppm, formaldehyde MAK=0.5 ppm, TWA=1 ppm, STEL=2 ppm) the working areas must be well ventilated.

Corrosion-resistant or enameled steel is used as the *construction material* for phenolic resin plants.

Emptying the reactor vessel is not problematic for dissolved, low viscosity resins. For solid phenolic resins – particularly resols with a high melt viscosity – rapid emptying and cooling of the resin is very important to avoid further condensation. Besides emptying into pans, removal by cooling conveyors or Pastillier machines has come into use. Phenolic resins which cannot cross-link, such as novolacs or alkylphenol resols, are also worked up in thin-layer evaporators or other continous evaporation plants.

In general, phenolic resins are produced in very small quantities of a very great variety of types, so that batchwise processes are more economic. Some types, e.g., novolacs for thermosets, or resols for the production of wood glues, are, however, produced in large quantities so that a continuous process is more favorable from the point of view of both obtainable throughput and properties of the substance. Processes described in the literature suggest the use of tubular reactors and series of tank reactors [13], [14].

4.1. Novolacs

In the formation of novolacs, substitution and condensation reactions occur simultaneously. In large reaction vessels formaldehyde is metered to a phenol – catalyst mixture and the rate of addition is controlled depending on the heat evolved for safety reasons. When using smaller vessels, even under laboratory conditions, care must be taken because of the exothermic reaction.

Under industrial conditions, analytical control of the course of the reaction is not necessary, because the degree of polycondensation and molecular structure of the resin are determined by the reaction conditions and the concentration of the starting materials. A temperature – time program is usually used.

Example [11]: 1880 parts of phenol are melted in a reaction vessel to which 50 parts of oxalic acid are added and heated to 100 °C. 1560 parts of an aqueous 30 % formaldehyde solution are then gradually metered in over ca. 2 h. The reaction mixture is held at 98 °C for 5 h and the volatile parts are then distilled off under reduced pressure, until a residue temperature of 160 °C is attained at a pressure of 2.0 kPa. 1968 parts of a novolac with a softening point of 124 °C remain in the vessel.

4.2. Resols

Resols from Trifunctional Phenols. The production of resols differs from that of novolacs in that the reactions between phenol and formaldehyde are not allowed to go to completion but are stopped at the stage where auto-cross-linking

Figure 1. Phenolic resin plant
a) Outlet tap; b) Heating; c) Stirrer; d) Evacuation system; e) Thermometer; f) Reflux condenser; g) Main condenser; h) Three-way tap; i) Reflux and separation vessel; j) Reflux return with siphon; k) Receiver

resols are still liquid or soluble. The continuation of the condensation reactions beyond the resol stage (*A-stage*) leads to resins which are no longer soluble but can only be swelled and which are known as *resitols* (*B-stage*). The final cross-linking to form *resites* (*C-stage*) gives completely cross-linked plastics.

In resol production, the concentration of formaldehyde and the degree of condensation must be controlled during the reaction. The degree of condensation is controlled by measurement of the viscosity, if necessary, after dilution with solvents. Other possibilities include the determination of solubility, melting point, and B-time (see section 6). The reaction temperatures for the production of resols are between room temperature and ca. 100 °C. The molar ratio of phenol to formaldehyde can vary widely. The upper limit is determined by the functionality of the phenol towards formaldehyde (i.e., a molar formaldehyde – phenol ratio of 3:0). Resols are also formed, however, if an excess of phenol is used. In this case a major portion of the phenol does not react.

The reaction is controlled by the type and quantity of catalyst used and the temperature. High alkali concentrations (up to 1 mol per phenolic hydroxyl group) in combination with low temperatures promote the formation of hydroxymethyl groups and stabilize them. Low catalyst concentrations and high temperatures particularly promote the condensation reactions.

The catalyst can remain in the resin and – in the case of alkali hydroxides – render it water-soluble. These catalyst-containing resols can be used industrially. The catalysts can also be neutralized and, if necessary, removed by washing out or filtration. The resols thus lose their water-solubility partially or completely and must then be employed in polar organic solvents.

The heat of formation of hydroxymethyl groups is only −20.3 kJ/mol, as compared with −98.7 kJ/mol for the formation of methylene bridges [11]. Thus, the heat of formation of resols is theoretically lower than that of novolacs. However, hydroxymethyl groups are only stable at low temperatures and can be converted into methylene bridges at higher temper-

atures. Therefore, in the production of resols a great quantity of heat is evolved if the reaction gets out of control. As a result of the high formaldehyde–phenol ratio, resol production also has high safety requirements.

To *etherify* the hydroxymethyl groups, a solution of the resol is heated in, for example, butanol. The water formed is distilled off azeotropically with the organic solvent as entrainer which is recycled to the reactor. Condensation reactions between the hydroxymethyl groups to form ether bridges occur simultaneously. The reaction is controlled by measurement of the viscosity and the solubility. Etherification of alkyd- and oil-modified phenolic resins should be carried out in the presence of a plasticizer, because the compatibility between the reaction components is thus established more quickly. The distillative removal of solvents or water may be necessary during the various reaction stages or as a final step. During the distillation the condensation reactions continue. Distillation must therefore be carried out under mild conditions.

Example [11]. *Condensation*: 846 g (9 mol) phenol and 1600 g formaldehyde solution (30 %, 16 mol) are mixed at 20 °C and the pH adjusted to 9.5 – 10 by addition of concentrated aqueous sodium hydroxide solution with stirring (ca. 110 mL 38 % sodium hydroxide). The mixture is heated to 60 °C and kept for 4 h at this temperature. The decrease in formaldehyde concentration is monitored by titration with hydroxylamine hydrochloride. At the end of the reaction only ca. 1 % formaldehyde is present. The mixture is cooled, and carefully neutralized almost completely with ca. 5 % hydrochloric acid with stirring. The reaction solution must not become acidic and should have a pH of ca. 7.2 – 7.5. Water and excess phenol are subsequently distilled off in vacuum, such that the inner temperature may reach 60 °C at maximum (at 1.5 kPa). 1360 g of viscous resin is obtained as residue.

Etherification: 1360 g butanol and 125 g toluene are added to the residue and the mixture is stirred at 40 °C until the components have completely dissolved. After cooling, precipitated sodium chloride is filtered off. 900 g butanol are then added to the filtrate and the pH ist adjusted to 6 with a concentrated solution of phosphoric acid in ethanol with vigorous stirring. The reaction mixture is then heated to boiling with stirring in a three-necked flask fitted with a Dean–Stark head which is filled with a 1:1 butanol–toluene mixture. In the Dean–Stark head, the water which has been distilled off is separated and the solvent is recycled into the reaction vessel. After ca. 72 mL water have been distilled off, a sample of the reaction solution can be diluted at 20 °C with 4 parts of xylene or 1.4 parts of petroleum ether without the resulting solution becoming cloudy (before the etherification a sample could only be diluted by 0.7 or 0.4 parts, respectively). The solution is concentrated to 2620 g in vacuum and traces of salt are filtered at 20 °C after 48 h.

Alkylphenol Resols. *para*-Alkylphenols can only react with formaldehyde in the *ortho*-positions. Hydroxymethyl groups or dimethylene ether bridges in the *ortho*-position differ from those in the *para*-position by their greater stability. In the production of alkylphenol resols the hydroxymethyl groups therefore remain relatively stable in alkaline medium even at elevated temperatures of between 60 and 70 °C. To prevent the conversion of dimethylene ether bridges to methylene bridges according to Equation (6), see page 3, the production of alkylphenol resols is often performed in two steps. In the first step, a resin rich in hydroxymethyl groups is produced in the presence of alkali. The catalyst is subsequently removed by neutralization and washing out. The substance is then heated to >100 °C to carry out the actual polycondensation, the etherification of hydroxymethyl groups to form dimethylene ether bridges. Catalysts are not required in this step.

4.3. Phenolic Resins Modified by Natural Resins

The reaction of preformed resols with rosin to give albertol acids (see page 3) is carried out in a melt at 100 – 200 °C. The albertol acids are subsequently reacted with polyols to give polyesters or with metal oxides to give resinates (both procedures can also be combined). These reactions must be carried out at temperatures of up to 280 °C because the tertiary carboxyl groups of the abietic acids are only esterified slowly and the melt viscosities and softening

points of the rosin-modified phenolic resins can be very high. Suitable resol components are the reaction products of formaldehyde with phenol, cresols, alkylphenols, or bisphenol A, or mixtures of these. The properties of the resins are determined by the composition and structure of the resol, the resol – rosin ratio, and the nature and quantity of the polyols or metal oxides used for the subsequent reaction. The modified phenolic resins vary greatly with respect to viscosity, softening point, miscibility with solvents, and compatibility with varnish or printing ink raw materials.

The reaction sequence between rosin, resol, and esterification components can also be reversed. In this case the natural resin acids are first esterified and the esters are then reacted with resols.

4.4. Phenolic Resins with Special Properties

Resols for Water-Soluble Varnishes. Water-soluble resols are water-soluble in the form of their phenolates. These phenolates are not suitable for varnishes because they do not form adhesive varnish films. For the production of self-cross-linking binders for water-soluble varnishes, carboxyl groups are introduced into the preformed resols. These carboxyl groups are rendered water-soluble by salt formation with amines or ammonia. The phenolic hydroxyl groups are reacted with chloroacetic acid according to the Williamson ether synthesis usually at the temperature of formation of the resol. Alkali is used as the condensation agent. To achieve water-solubility it is not necessary to introduce carboxyl groups into all resol molecules. The reaction is generally carried out in the presence of auxiliary solvents, mostly glycol ethers, which then also remain in the varnish formulation [15].

Water-soluble phenolic resins for varnishes are mostly applied in combination with plasticizers, for example epoxy resins or fatty oils. It is thus often sufficient to incorporate the groups that impart water-solubility into one of the components. The other component is carried into the aqueous phase by the former component.

Ether Resins from Resols and Novolacs. The phenolic hydroxyl groups can be etherified with, e.g., benzyl chloride or allyl chloride. The etherification always lowers the rate of curing. On the other hand, it reduces disadvantages which are due to the presence of phenolic hydroxyl groups, e.g., oxidizability, tendency towards coloration, and sensitivity towards alkalis. A strong decrease in viscosity is often associated with etherification. This is particularly the case with allyl ethers. The phenolic hydroxyl groups of resols and novolacs can also be etherified with epoxy compounds such as ethylene oxide, propylene oxide, or styrene oxide in the presence of catalytic quantities of alkali. The nucleophilic opening of the oxacyclopropane ring by the phenolic hydroxyl groups is very fast. It is thus possible to work in aqueous solution without significant nucleophilic attack of water at the epoxy group. Reaction of the epoxy compounds with hydroxymethyl groups only occurs if the epoxy compound is added in a nearly stoichiometric ratio to the phenolic hydroxyl group.

Condensation Reactions between Phenol Ethers or Hydrocarbons with Formaldehyde and Phenol. Preformed phenol ethers can form polycondensates with formaldehyde. Known examples are diphenyl ether, phenoxyacetic acid, diphenylglycerol ethers, and phenoxyisopropanol. The condensation reactions can only be carried out with acid catalysts. Depending on the polarity of the ether, strong acids must be used, sometimes in very large quantities. Aromatic hydrocarbons, e.g., xylene, are even less reactive than phenol ethers. The hydroxymethyl groups and dimethylene ether bridges are fairly stable in the phenol ether resins in spite of the high acid concentration and remain as reactive groups in the resin.

Because of the low tendency towards self-curing, these resins are not used for self-cross-linking, but are usually reacted with (excess) phenol to form methylene bridges between phenol ether (or hydrocarbons) and phenol.

4.5. Wastewater

In the production of phenolic resins phenol-containing wastewater is produced, which can also be contaminated by formaldehyde, salts, acids

and alkali, and organic solvents. They must be rendered harmless in a way that will not pollute the environment, for example by incineration. In addition, phenol can be degraded very readily by bacteria. The purification in biological sewage plants – after dilution with other wastewater, if necessary – is therefore very effective. It can be economic to extract the phenol before the incineration of the wastewater.

5. Storage and Transportation

Solid phenolic resins which are sold in broken pieces, flakes, pastilles, or granules, can be packed in sacks, drums, or large containers. If the resins (e.g., rosin-modified types), have a tendency towards autoxidation, they should be stored in the absence of oxygen. *Phenolic resin solutions* are not corrosive and can therefore be stored in iron containers, if a possible coloration of the resin is acceptable. Otherwise the containers must be coated on the inside. *Liquid phenolic resins* are transported in tank cars, containers, or tank pallets. When stored at room temperature, aqueous alkaline resol solutions often lose their viability after a few days or weeks. These solutions must be kept cool during transportation and stored in refrigerated areas. The storage life of solid resols at room temperature is generally longer: it is nevertheless advisable to keep all resols cool during storage. Certain phenolic resins have relatively low softening temperatures and compact during storage which impairs their storage stability.

6. Testing and Analysis

A summary of the testing methods is contained in DIN 16 914 (draft version).

General Investigations. Color index, viscosity, flash point, density, melting point (softening point), and free formaldehyde content are measured according to DIN 53 244. When *free formaldehyde* is determined by the hydroxylamine method, solvents can be used for dissolution of the resins. The blank value of the solvent must be taken into account.

Free phenol is measured photometrically according to DIN 53 704 after steam distillation. Phenol can also be determined bromometrically by bromination of the aromatic nucleus, however side-chain bromination can occur as well and can give values for the phenol concentration which are too high.

Determination of *water* is carried out by the Karl Fischer method.

Hydroxyl Groups. The total quantity of hydroxyl groups is determined by acetylation according to DIN 53 240. The presence of unsaturated groups, for example in modified natural resins, can give rise to values which are too high.

Reactivity Determination for Resols: B-Time. The cross-linking rate of resols, the transition from the A- into the B-stage is determined on a thermostatted heating plate at a predetermined temperature, usually 120 or 150 °C.

The content of hydroxymethyl groups and dimethylene ether bridges in alkylphenol resols is determined by reaction with an excess of phenol and subsequent determination of the water liberated (Karl Fischer method) or the quantity of phenol that has reacted [16].

Differentiation between the Various Types of Phenolic Resin. Neutral resol solutions in polar solvents give a blue or purple coloration with iron(III) chloride. With novolacs this coloration only appears after the addition of a small amount of hexamethylenetetramine. Alkylphenol novolacs often give a black-violet coloration. Modified natural resins do not show the color reaction, but can be identified by the Storch – Morawski color reaction (→ Resins, Natural) [17], [18].

Chromatographic Methods. Thin layer chromatography is very suitable for the determination of phenolic resins (e.g., monomer content) and can also be used for the quantitative determination of components by comparison of the spot size. The sodium salt of diazotized sulfanilic acid in aqueous solution, or iodine vapor are used to develop the spots.

Gel permeation chromatography on polystyrene columns is applied to determine the molecular mass distribution of phenolic resins. In the low molecular mass range it also gives information on the concentration of phenols, hydroxymethylphenols etc. The columns must be calibrated with phenolic compounds [19].

Gas chromatography is suitable for the determination of free phenols. Phenols up to and including butylphenol can be detected by direct injection. Higher phenols are determined after esterification (acetylation, silylation).

Spectroscopic Methods. IR spectroscopy of phenolic resins is described in detail in [10]. The groups typical of phenolic resins can be determined and analyzed semiquantitatively.

Phenolic resins show UV absorption bands at 254 and 280 nm. UV spectroscopy is sometimes used for product monitoring, whereby however, the shift of the bands due to other resin components or because of substitution must be taken into account.

NMR spectroscopy enables detailed examination of the molecular structure of phenolic resins and at the same time kinetic studies of the formation reactions under different conditions [20].

7. Uses

7.1. Novolacs

7.1.1. Cross-Linked Novolacs

For cross-linking, novolacs are processed together with *curing agents*, mainly hexamethylenetetramine. Cross-linking occurs at a sufficient rate at 140 – 160 °C and can be carried out within a few minutes, particularly if a part of the polycondensation reaction has already taken place.

Novolacs are sometimes cross-linked with *resols*. This reaction gives resins with high hardness, high stability, but a very low fracture strain.

The deflection under load is tested according to Martens. According to DIN 53 458 and DIN 53 462, the fatigue strength at elevated temperatures is determined from properties such as the weight loss after storage in air or under an inert gas. Cross-linked phenolic resins are much less inflammable than thermoplastics. Phenolic resins can be rendered virtually nonflammable by the addition of usual plastics additives such as phosphates, borates, halo compounds, red phosphorus, phosphoric acid esters, or antimony trichloride. This is particularly important if other inflammable substances are used as fillers or for reinforcement.

Thermosets. Phenolic resin molding materials are produced with heated rollers or extruders. Treatment of a mixture of novolac, hexamethylenetetramine, fillers, and additives leads to an intermediate, the actual molding material. The polycondensation is driven so far that the molding material in the final molding step can still flow, but so that the final cross-linking occurs very quickly. Phenolic resin thermosets are standardized according to DIN 7708, part 2. The application properties of the final products depend very much on the choice of filler material. The processing properties, in contrast, are affected primarily by the novolacs used. Especially important processing properties are good flow characteristics and rapid curing. Molding technology which predominated until the end of the 1960s has in the meantime been substituted by transfer molding and injection molding, particularly in the mass production of less complicated preforms. Thus the expression "thermosetting molding materials" has come into common use.

Grinding Wheels. In the production of phenolic resin-bound grinding wheels, the grinding material (usually corundum of various granularities) is impregnated with a liquid phenol resol and mixed with a ground, pulverized mixture of phenol novolac and hexamethylenetetramine. The binder cures to a three-dimensional cross-linked resite under a carefully controlled temperature and pressure program. No defects may occur in this process because grinding wheels are exposed to high thermal and mechanical stresses (DIN 69 100, DIN 69 111).

Friction Linings. Brake linings and clutch facings are made of reinforced phenolic resin-bound thermosets. Novolac – hexamethylenetetramine mixtures can also be used here as binders. For better heat conduction, copper wire or copper gauze is often incorporated. Novolacs modified with alkylphenols or cashew oil are used to adjust hardness and lubricating properties, particularly in brake linings.

Reinforcing Resin for Rubber (→ Rubber, 4. Chemicals). The hardness of rubber is increased by the incorporation of novolac – hexamethylenetetramine mixtures. This hardness can be so great as to enable fabrication of solid, tough molded articles, for example for bodywork parts. Often, however, as in car tire mixtures, only slight improvement of the rubber hardness is aimed at. The reinforcing effect is thought to be caused by strong intermolecular interactions between the cured, duroplastic

phenolic resin and the rubber-elastic vulcanized product. Both types of macromolecule are not bonded by covalent bonds.

7.1.2. Novolacs without Cross-Linking

The use of novolacs which are not cross-linked is less important and is based particularly on their solubility and compatibility properties. As polyalkylidenephenols they have strong inter- and intramolecular interactions and can be adapted to the most varying requirements by alkyl substitution.

Varnishes (→ Paints and Coatings, Chap. 2.13.2.). The use of non-cross-linked novolacs in varnishes is the oldest application of phenolic resins. Because of their high susceptibility towards oxidation and coloration, particularly in the case of unsubstituted phenol novolacs, this application area has hardly developed further. Non-cross-linked novolacs are now only important in specialist areas such as model lacquers and bituminous paints.

Printing Technology. Novolacs are often added to aniline printing inks because of their high affinity for these dyes. Because aniline printing inks are often used for printing on food packaging materials, the novolacs must be phenol-free. Novolacs are also used in the formulation of ballpoint pastes.

Novolacs are applied together with diazo compounds to zinc or aluminum plates in a thin layer for production of positive offset printing plates (→ Imaging Technology, Chap. 3.2.). Similar systems are used as photoresists for the photolithographic production of integrated circuits (→ Imaging Technology, Chap. 4.).

Raw Materials for Epoxy Resins. The reaction of epichlorohydrin with novolacs (instead of bisphenol A) leads to polyfunctional epoxy resins (→ Epoxy Resins, Chap. 2.2.2.). Their curing products are characterized by their particularly high usage temperatures.

Alkylphenol novolacs, particularly those based on 4-hydroxybiphenyl, 4-isooctylphenol, and formaldehyde are used for the production of copying paper.

Tackifiers for Rubber (→ Rubber, 4. Chemicals). Nonvulcanized rubber mixtures are often not tacky enough to adhere to each other. This is a considerable disadvantage in the production of laminated rubber articles, e.g., car tires. Tackifiers are used in rubber technology to improve this. Besides mineral oils and natural and synthetic resins, alkylphenol novolacs are particularly effective and when used with other tackifiers have a synergistic effect. In addition to alkylphenol – formaldehyde novolacs, *para*-alkylphenols – acetaldehyde resins, and *para*-alkylphenols – acetylene resins are often used as tackifiers.

Crude Oil Separators. Ethoxylation (i.e., reaction with ethylene oxide) of alkylphenol novolacs gives water-soluble, surface-active substances. If the degree of ethoxylation is suitably adjusted, they have de-emulsifiying properties. Addition of small quantities to the crude oil that is extracted as an oil – saltwater emulsion effects a faster separation into an oil and an aqueous phase.

7.2. Resols

7.2.1. Water-Soluble Resols

Condensation products of phenol and formaldehyde, which are present as water-soluble phenolates, are used mainly as adhesives for wood or wood chips, as binders for organic and inorganic fibers and for granular material such as corundum or sand. Curing is performed thermally at 100 – 180 °C and, if possible, under pressure. If curing is carried out under atmospheric pressure, the cross-linking process must be carefully controlled and performed slowly to avoid the formation of bubbles or cavities.

The waste-gas from the thermal curing process contains phenol, formaldehyde, and sometimes solvent vapors. When legally stipulated limiting values are exceeded, the waste-gases must be incinerated.

Cross-linked phenolic resins have a low flammability. They can be rendered virtually nonflammable by additives. In the event of fire the flue gases are relatively nontoxic and, compared to the flue gases from other burning plastics, are relatively transparent. This makes them particularly suitable for the interiors of vehicles, places of assembly etc.

Chipboard Adhesives. The greatest quantity of aqueous, alkaline resol solutions are used in the production of wooden chipboard. Chipboard

bound by phenolic resin is moisture-resistant in contrast to that bound by urea resins, and is therefore suitable for the production of exterior walls in buildings and related uses.

Construction Adhesives. Resorcinol – formaldehyde resins are used as wood glues. Resorcinol is treated with a substoichiometric amount of formaldehyde in an alkaline medium and the stable solution is treated with more formaldehyde (usually in the form of paraformaldehyde) immediately before use. The polycondensation with resorcinol, which is very fast at, and even below, room temperature is thus restarted. The resorcinol – formaldehyde resin cross-links three-dimensionally. Glueings containing resorcinol resins have high mechanical stability and are highly water-resistant.

Binding Agents for Molding Sand (→ Foundry Technology, Chap. 2.3.4.). Phenol resols or novolac – hexamethylenetetramine mixtures which can be sufficiently diluted with water, are used as binders for casting molds, which consist mainly of sand. Mixtures of both resins are sometimes used for full molds. For hollow and thin-walled molds (Croning process), alcoholic solutions of novolac – hexamethylenetetramine adducts are used. To achieve special properties or to make the process cheaper, phenolic resins are sometimes modified with furan or urea resins.

Laminates. High quality laminates for electrical equipment are obtained by impregnation of paper with phenolic resins and subsequent thermal cross-linking. They are used as insulation and construction materials. Unmodified resols and oil-plasticized resols are used together for impregnation. Both resins have different functions. The unmodified resins – with as low a molecular mass as possible – penetrate into the fiber and the oil-plasticized resins remain on the fiber surfaces and bind them together.

In *decorative laminates*, water-soluble, alkaline resol solutions can only be used for the production of core resins because of their dark coloration. Melamine resins are used as decorative facings.

Fiber Bonding. Organic or inorganic fibers or rock wool can be bonded to plates or nonwoven fabrics by impregnation with an aqueous resol solution or this can be sprayed on them. Curing is carried out continuously with heated rollers or in presses. Matting or insulating plates bound with phenolic resin have heat-insulation properties similar to thermoplastic foams, but have the advantage of being virtually nonflammable and at the same time soundproof.

Foamed Plastics (→ Foamed Plastics, Chap. 4.4.). Water-soluble resols can be used for the production of foamed plastics after neutralization and, if required, removal of the basic catalyst. For foaming, the addition of surfactants and the use of blowing agents (i.e., low-boiling or halogenated hydrocarbons) is necessary. Phenolic resin foams have the advantage of low flammability. However, the corrosive effect of the strong acids used as hardeners limits their general use.

Abrasives. To produce abrasives such as sandpaper, abrasive cloth, or flexible sanding disks on vulcanized fiber, abrasive grains are applied to a moving backing cloth on one side. These grains are fixed together and to the surface of the backing cloth with a binder. For heat-resistant abrasives, phenol resols are preferably used as binders.

Since the carrier material (usually cellulose) is sensitive to high temperatures, a prolonged application of temperatures $>130\,^{\circ}C$ must be avoided. Therefore, cross-linking of the phenol resol to resite takes a long time. Phenolic resins that are suitable for the production of abrasives must therefore be very reactive, to limit the curing time to a few hours. This naturally limits their storage life. The cross-linking reactions are carried out under atmospheric pressure in sloping dryers and the carrier materials, coated with phenolic resin, and abrasive grains are introduced in sloping loops through channels, whose temperature and humidity must be carefully controlled.

7.2.2. Resols in Organic Solvents

The resols produced as aqueous alkaline solutions can be dissolved in polar solvents after neutralization of the catalyst. Basically such solutions do not differ from aqueous solutions. Catalysts can be added to accelerate cross-linking. Since, however, phenolic resins are often used in combination with other components, these resins must be compatible with the other substances, and for this purpose their solution properties must be altered. This can be done using alkylated phenols as raw materials or in the

etherification of the methylol groups with alcohols.

Epoxy Resin – Phenolic Resin Coatings. Resols based on cresols are used in cross-linking together with expoxy resin. The enamels baked at temperatures around 200 °C stand out by virtue of their very good ductility and very high chemical stability. They are principally used for the inner coating of food and drink cans, and other containers.

Oil-Plasticized Resols. Resols – mainly based on cresol or bisphenol A – are modified by fatty oils or alkyds and are used as baking enamels. These varnishes have good chemical stability and very high ductility and are used, in particular, as inner coatings for containers. Other uses of oil-plasticized resols lie in the area of cylinder-heat gaskets and electric insulation materials.

7.2.3. Alkylphenol Resols

Resols from *para*-alkylphenols are also soluble in nonpolar solvents. The solubility increases with increasing size of the alkyl group. *para*-Alkylphenol resols differ from other resols in their bifunctionality towards formaldehyde. Thus, *para*-alkylphenol resols cannot cross-link by themselves, but are used as cross-linking agents for other, polyfunctional substances. Examples are fatty oils, rubbers, long-chain epoxy resins, alkyd resins, and phenol novolacs.

Vulcanization. Rubbers can be vulcanized by alkylphenol resols. As phenolic resins are considerably more expensive than sulfur, this possibility is only exploited for special cases, e.g., butyl rubber.

Adhesive Resins. The properties of polychloroprene adhesives can be improved by natural and synthetic resins. Alkylphenol resols not only increase the stickiness of the adhesive but also its binding and heat stability. Since the amount of resin needed to be added is about half the quantity of polychloroprene, adhesive resins have considerable economic importance.

The alkylphenol resols do not act as such in polychloroprene adhesives but in the form of their magnesium and zinc complexes. These are formed with the magnesium and zinc oxides present in the polychloroprene adhesive. The complexes described as chelate polymers have a very high molecular mass, but are nevertheless readily soluble in aromatic hydrocarbons and even in naphtha [21].

7.3. Phenolic Resins Modified by Natural Resins

Printing Inks. The rosin-modified phenolic resins are used as binders for book or offset printing inks for the following reasons: (1) They are soluble in mineral oil and aromatics, (2) compatible with other printing-ink raw materials, and (3) have a high melting point, which allows a rapid transition from the liquid to the solid state on printing. Phenol resins modified by natural resins are very varied so that they can be adopted to the continually increasing rate of working in the production of printed articles.

7.4. Waterborne Paints, Phenol Ether Resins

Waterborne Paints. The amine and ammonium salts of resols containing carboxyl groups are water-soluble. They are used as baking enamels and give coatings which are resistant to chemicals but are brittle. To plasticize them they are mixed with fatty oils, alkyds, or unsaturated hydrocarbons (which have been rendered water-soluble by the addition of maleic anhydride and subsequent salt formation). Their main use lies in the electrodeposition coating of car bodies and vehicle parts. See also, → Paints and Coatings, Chap. 2.13..

Allyl Ether Resols. Resols etherified with allyl groups at the phenolic hydroxyl group have a very low viscosity and can be used as solvent-free or low-solvent binders in varnishes. Higher baking temperatures must be used for cross-linking than in the case of simple phenolic resins.

Phenol Ether and Hydrocarbon – Formaldehyde Polycondensates. Mixed condensates from (1) phenol ethers – formaldehyde – phenol, or (2) hydrocarbons – formaldehyde – phenol are used in thermosets which have an increased stability towards chemicals and oxygen.

Table 1. Phenolic resin production in the United States

Year	Production, t/a	Proportion of duro-plastics, %	Proportion of all plastics, %
1978	728	36	6.1
1980	675	37	5.6
1982	902	47	7.4
1984	1126	45	7.4
1986	1231	47	7.3
1988	1380	47	6.9

7.5. High-Temperature Coking

Phenolic resins, whether resols or novolacs, coke upon heating in the absence of oxygen. They can therefore be used as binders for refractories based, for example, on magnesite or dolomite, which are used for the lining of blast furnaces and similar constructions. Phenolic resins can also be used as high-temperature materials after coking and in some cases graphitization. These materials can be reinforced with temperature-resistant fibers.

8. Economic Aspects

In 1978, 728 000 t phenolic resin were produced in the United States [22] and in 1994, 730 000 t [23]. The development of production since 1978 and the proportion of phenolic resins in the production of all plastics in the United States is shown in Table 1.

In the Federal Republic of Germany the phenolic resin market did not develop to the same extent. Excluding phenolic resins modified by natural resins and thermosets, production was ca. 230 000 t in 1989 compared with 180 000 – 200 000 t in 1978. Of this ca. 35 % is used by the wood industry in the form of glues. 20 % are needed for the production of casting molds and molding materials (free market) and 10 % each for the production of fiber matting, brake linings, and grinding agents. 3 % each go into the paints and coatings industry, the adhesives industry, and the production of battery separators.

No conclusions about the turnover value can be drawn from the quantity data, for although phenolic resins for mass applications are cheap, very high prices are often demanded for specialist applications.

9. Toxicology and Occupational Health

Cured phenol – aldehyde resins are classified as nontoxic. The toxicity of phenolic resins is therefore assessed according to their content of unreacted phenol [24]. In the Federal Republic of Germany phenolic resin formulations with a content of more than 5 % free phenol must be labeled with a skull and crossbones and those with more than 1 % with a St. Andrew's cross. Substances liberated in the thermal cross-linking of phenolic resins, particularly formaldehyde, are toxic and lead at least to irritation. Contact with phenolic resins can lead to allergies in sensitized people.

Occupational Health. No TLV or MAK values have been established for phenolic resins. The corresponding values of the most important monomers are as follows: formaldehyde TLV-TWA 1 ppm (1.2 mg/m^3), TLV-STEL 2 ppm (2.5 mg/m^3), MAK 0.5 ppm; phenol TLV-TWA 5 ppm (19 mg/m^3), MAK 5 ppm.

1. Introduction

Phenothiazine (**1**) [*92-84-2*] (10*H*-dibenzo-[*b, e*]-1,4-thiazine) was first synthesized by BERNTHSEN in 1883 [1]. The chemistry of phenothiazine derivatives has since assumed considerable importance due to the diversity and number of compounds synthesized and the many products exhibiting extremely important therapeutic properties.

The atoms in the phenothiazine ring (**1**) are numbered as follows [2]:

1

Phenothiazines have been reviewed [3]. More detailed information is to be found in [4–29].

2. Uses and Biological Activity

Physical properties of the compounds discussed in this chapter are listed in Chapter 4.

2.1. Therapeutic Uses

Work carried out by LAUTH [30] and BERNTHSEN [31] revealed evidence of the anthelmintic properties [32], [33] of phenothiazine (**1**) and the antimalarial properties [34–36] of derivatives such as methylene blue (**2**) [*61-73-4*], which were also used as dyes (→ Azine Dyes, Chap. 4.1.) and antiseptics [37–39].

2

However, it was only with the work of CHARPENTIER [40], [41] that any real interest was shown in 10-aminoalkyl phenothiazine derivatives, thereby revealing the versatility of phenothiazine as a pharmaceutical.

Antihistamines. The discovery of the role of histamine in biological processes [42] allowed the development of bioassays (e.g., isolated ileum spasm) that led to the discovery of the first synthetic antihistamines such as phenbenzamine [43].

Aminoalkyl groups were shown to have various biological activities (e.g., antimalarial, antihistamine, antispasmolytic). These groups were therefore condensed onto phenothiazine to obtain new antimalarial agents. However, the resulting derivatives were found to be of no use as antimalarials [44], but had useful antihistamine activity [45].

These investigations terminated in the synthesis of promethazine (**3**) [*60-87-7*], followed by many other products; some examples are given in Table 1 (see also → Antiallergic Agent).

Oxomemazine (**7**) [*3689-50-7*] (RP 6847, Dysedon, Doxergan) [50] and isothipendyl (**8**)

7

8

Antiparkinsonism Agents. Utilization of the inhibitory properties of certain phenothiazines on the extrapyramidal motor system [52] has led to the development of products with anticholinergic properties that are used to treat Parkinson's disease. Examples are diethazine (**9**) [*60-91-3*] (RP 2987, Diparcol) [53], and ethopromazine (**10**) [*522-00-9*] (RP 3356, Parsidol) [54] (see → Parkinsonism Treatment, Chap. 2.1.3.).

9

10

Neuroleptics. The discovery of neuroleptics resulted from numerous investigations on the physiopathology of the autonomic nervous system [55], [56]. Laborit perfected anesthesia and artificial hibernation by using " cocktail-lytics" [57], [58]. He recognized the advantage conferred by certain antihistamines (in particular promethazine) in these mixtures on account of their "hypometabolizing, hypnotic, analgesic, and antithermic properties." This advantage and the powerful potentiating activity of these products on the action of barbiturates [59], [60] led to the investigation of phenothiazines with a pronounced action on the central nervous system (CNS), but with a greatly reduced antihistamine activity.

The usefulness of chlorpromazine (**11**) [*50-53-3*] [61] was first demonstrated in anesthesiology and in the treatment of operative shock [57] as an " autonomic stabilizer" [61]. However, it was soon recognized that the major importance of this product was in psychiatric therapeutics [62–65]. Chlorpromazine was thus the first representative of a new class of drugs used to treat psychoses, namely the major tranquillizers (neuroleptics).

Table 2 gives some examples of neuroleptics (see also → Psychopharmaceutical Agent).

Some neuroleptic phenothiazines have a very prolonged action. Examples include the heptanoate ester of fluphenazine (**20**) (Moditen-Retard [*2746-81-8*]) and the palmitate ester of pipotiazine (**22**) (Piportil M 2). The latter compound can be administered as a single monthly intramuscular injection [82].

The field of neuroleptics has stimulated research aimed at elucidating and characterizing pharmacological profiles for the discovery of

other types of psychotropic drugs. Neuroleptic phenothiazines can interact with a large number of aminergic (e.g., dopaminergic, histaminergic, adrenergic) or enzyme systems, and have been used as tools in attempting to understand the physiopathology of psychotic disease [83–97]. The interactions involved have still not been elucidated in detail.

Antiemetics. The exploitation of the activity of certain phenothiazines in inhibiting apomorphine-induced vomiting in dogs [98] has resulted in excellent antiemetic products for use

in humans (hepatodigestive system, pediatrics, drug intolerance, etc.). Examples are metopimazine (**26**) [*14008-44-7*] (RP 9965, Vogalene) [99], [100] and prochlorperazine (**18**) [101] (see also → Antiemetics, Chap. 3.).

26

Anti-Inflammatories. Certain phenothiazine products such as metiazinic acid (**27**) [*13993-65-2*] (RP 16091, Soripal) [102] are used as nonsteroidal anti-inflammatory agents.

27

Other Therapeutic Effects. Some phenothiazine derivatives possess activities that have resulted in their use in special therapeutic applications. Table 3 gives examples.

Other products have also been the subject of clinical cardiovascular studies. They include chloracizine (**31**) [*800-22-6*] (G-020, RP 11504, Chlorocyzin) as a coronary vasodilator [106], and moricizine (**32**) [*31883-05-3*] (EN-313, Ethmosine) as an antiarrhythmic agent [107–109].

31

32

Numerous studies have been published on the potential use of phenothiazines as anticancer drugs [110–112]. Veterinary applications have also been described [113], [114].

Certain phenothiazines with antidepressant properties (uptake of noradrenaline, serotonin) have stimulated research on other tricyclic compounds, resulting in the discovery of powerful antidepressants such as imipramine.

2.2. Biological Activity

A brief summary of the numerous biological fields in which phenothiazines are of interest will now be given to explain both their versatility as pharmaceuticals and the motivation of future research.

Binding to Receptors. The pharmacological profiles of phenothiazines that have been the subject of a therapeutic application are often correlated with their agonistic or antagonistic interaction with neuronal transmitter receptors: dopamine D_1 [115] and D_2 [116], histamine H_1 [117], adrenergic α_1 and α_2 [118], muscarinic (cholinergic) [117], and serotoninrgic [118] receptors.

Binding to other receptors of the neuronal system has also been noted, including the opiate receptor [119]. The product RP 60180 (**33**) [*128182-96-7*], for example, has a good affinity for the κ opiate receptor [120], [121].

33

Some phenothiazines have a high affinity for nonneuronal receptors, such as plasma proteins (albumin [122], α_1-AG [123]), lipoproteins, tissues (e.g., muscle, liver), membranes, or proteins (e.g., calmodulin [124]).

Enzyme Inhibition. The interaction of phenothiazines with numerous enzyme systems has been studied [16]. Phenothiazines bind extremely easily to proteins in cell membranes [125] and affect the activity of the enzymes or the accessibility of substrates and cofactors. Numerous physicochemical studies have been

[b] [103]. [c] [104]. [d] [105]

carried out on a wide variety of systems (e.g., ATPase, calmodulin-dependent enzymes, "redox" enzymes). These interactions are often associated with the complex-forming or redox properties of phenothiazines.

Antitumor Activities. Numerous phenothiazines have been studied in oncology. They include dyes [126], psychotropic agents [127], products opposing pleiotropic resistance (resistance to penetration of drugs into the cells) [128] and, in particular, "mustard"-type alkylating agents [129], [130].

Structure – Activity Relationships and Molecular Modeling. Several reviews have been published on the structure – activity relationships of phenothiazines [131–133] using physicochemical approaches (e.g., X-ray analysis, NMR spectroscopic studies in solution). A study of the different molecular conformations (Chap. 4) and geometrical parameters is useful for interpreting selectivities observed in various biological fields. For example, it has been shown that the conformation of the chains in the 10-position plays an important role in neuroleptic activity [134], [135].

Conformational analysis using molecular modeling enables hypotheses to be proposed concerning the interaction of phenothiazines with their biological targets [136].

2.3. Other Uses

Phenothiazine dyes are covered elsewhere (→ Azine Dyes, Chap. 4.1. and → Sulfur Dyes). Phenothiazines are also used for analytical purposes as redox indicators [137–139] and as reagents in spectrophotometry [139], [140] and gravimetry [17].

3. Syntheses and Reactions

3.1. Ring Syntheses

Phenothiazines can be synthesized by cyclization of diphenylamines or diphenyl sulfides (Fig. 1).

Cyclization of Diphenylamines. The first synthesis of phenothiazine (**1**) was performed by reacting diphenylamine with sulfur [1]. This synthesis was substantially improved by using iodine as catalyst [141], which enabled the first synthesis of 2-chlorophenothiazine, the key intermediate in the preparation of chlorpromazine (**11**) [66], [142–144].

Cyclization of Diphenyl Sulfides. The cyclization of diphenyl sulfides is by far the most important method of phenothiazine synthesis: In the "classical" route, Y in Figure 1 is a halogen atom leading to Ullmann-type syntheses (Fig. 2). In the route where Y is a nitro group, synthesis involves a Smiles rearrangement (Fig. 2).

The starting materials of choice for the two methods are 2-halonitrobenzenes (**34**) and 2-aminothiophenols (**35**), respectively.

Reaction of 2-halonitrobenzene (**36**) with **35** in an alkaline medium yields the corresponding 2-amino-2′-nitrodiphenyl sulfides, which

Figure 1. Synthesis of phenothiazines by cyclization of diphenylamines and diphenyl sulfides
∗ see Section 3.2

Figure 2. Cyclization of diphenyl sulfides

are acylated (generally with formic or acetic acid). The phenothiazine is then obtained by the Smiles rearrangement [145–148]. The main factors governing the reaction are steric hindrance [149], dependency on the electrophilic nature of carbon [150], the acidity of the acylamino group that attacks the aromatic nucleus [147], as well as the nature of the base.

As an example, 2-chlorophenothiazine can be prepared by this method [151]:

The second main cyclization route for diphenyl sulfides starts by reacting 2-halothiophenols with 2-halonitrobenzenes (**34**) (Fig. 2) [152]. Reduction of the product yields 2-halo-2′-aminodiphenyl sulfides which give the phenothiazine by an Ullmann reaction via formation of a benzyne intermediate, or by a Smiles rearrangement [153].

2-Chlorophenothiazine is synthesized by this route [154]:

Finally, phenothiazines may be obtained by cyclizing 2-aminothiophenols (**35**) with 1,2-dihalogenated cyclic compounds. The main application of this method is the synthesis of azaphenothiazines [155–160]. For example [159]:

Cyclization with Benzoquinones. Another important synthesis route to the phenothiazine ring is cyclization of 2-aminothiophenols with chloroquinones [161–164]:

An example is [165]:

Other Cyclizations. Phenothiazinones may also be obtained by cyclization of 2-aminothiophenols with 1,3-cyclohexanediones [166]:

The reductive cyclization of 2-nitrodiphenyl sulfides with triethyl phosphite also yields phenothiazines [167], [168]:

This cyclization involves a rearrangement similar to the Smiles rearrangement. The same applies to cyclizations starting from azide derivatives [169], [170], which probably proceed via a nitrene intermediate and involve electrophilic attack:

Other reports of phenothiazine formation cited in the literature include the reaction of isopropyl dithiocarbonate with 4-chloro-3,5-dinitrotrifluoromethylbenzene [171] or syntheses of azaphenothiazines by thermal cyclization of 1,4-benzo[*b*]thiazine derivatives [172].

3.2. *N*-Substituted Phenothiazines

The main routes for the substitution of nitrogen in the 10-position of phenothiazines are summarized in Figure 3.

The first substitutions involving acyl (route 1) or alkyl groups (route 2) were described by Bernthsen [173] and Fränkel [174], see also [12]. These substitutions are performed with alkyl halides, acid anhydrides, or acid chlorides in an alkaline medium. The first phenothiazines having a tertiary alkylamine substituent in the 10-position were described by Gilman and Shirley [44]. Charpentier [40], [175], [176]

Figure 3. Routes for the substitution of nitrogen in the 10-position of phenothiazines

then synthesized this type of product and demonstrated their valuable pharmacological properties [177].

Route 3 involves decarboxylation of carbamates [178], [179].

In route 4, diaryl sulfides are alkylated, and the *N*-substituted products are then cyclized by the methods discussed in Section 3 [180].

As an example, chlorpromazine (**11**) has been synthesized by these four routes as well as via the 10-cyanoethyl derivative [181].

In route 2 (direct alkylation), the C_2 or C_3 chains of the alkylating agents may undergo rearrangement via a mechanism involving the formation of an aziridinium or an azetidinium compound. For example [40]:

A similar mechanism is observed in route 3 with the formation of an intermediate cyclic ammonium compound [67], [182]. Route 2, which proceeds by direct alkylation of the phenothiazine nucleus, is the most important reaction in synthesis.

3.3. *C*-Substituted Phenothiazines

Electrophilic substitution occurs preferentially at the 3,7-C>1,9-C positions for 10-alkyl phenothiazines, and at the 2,8-C positions for 10-acyl phenothiazines. This generally holds for alkylation [183], [184], Friedel – Crafts acylation [185], [186], electrophilic halogenation [187], [188], nitration via "NO_2^+" [189], and metallation. Metallation yields compounds that are difficult to obtain by other methods [190–193].

Nucleophilic substitution is governed by the fact that phenothiazine has a high electron density and can thus yield oxidized cationic species that are susceptible to nucleophilic attack in the 3,7-C positions [194].

Examples of such reactions are nitration via "NO_2^-" [195], [196], halogenation via "X^-" [197–199], and thiocyanation by the Kaufmann method [200].

3.4. Analogues and Miscellaneous Compounds

Recyclized analogues may be obtained by Friedel – Crafts reactions [201–203], for example [204]:

Table 4. Physical properties of phenothiazines

Benzo-condensed analogues, oxidized quinone forms, and polyhydro forms may be obtained by cyclization.

Many "aza" derivatives have been synthesized; examples are described in [159], [160].

Isothipendyl (**8**) is synthesized as follows [51], [205]:

8

Finally, phenothiazines can be oxidized (see Section 3.5) to sulfones with potassium permanganate [206] or hydrogen peroxide in acetic acid [207], [208], or to sulfoxides with hydrogen peroxide in ethanol [209] or with nitric acid [210].

Phosphorylated derivatives have also been synthesized [211].

3.5. Other Chemical Properties of the Phenothiazine Nucleus

Oxidation of phenothiazines produces free radicals and cations [212–215]. A large amount of work has been carried out on the elucidation of the electrochemical [216] and photochemical [217] reaction mechanisms and the relationships between the various oxidized species and products [218], [219]. The most important sequence may be formulated as [220]:

∗ See Section 3.3.

Since phenothiazines have a high electron density, they may form charge-transfer complexes [212] in the presence of electron acceptors such as iodine [221], quinones [222], or tetracyanoethylene [223]. Numerous radical cation salts may also be formed, for example with picric acid [224].

4. Physical Properties

Molecular Conformation. Various studies (principally X-ray diffraction [225], [226] and nuclear magnetic resonance [227]) have shown that the phenothiazine ring may have a planar, axial-boat (extra), or equatorial-boat (intra) conformation. These forms are all in equilibrium with one another in solution (Fig. 4) [228], [229].

Figure 4. Conformations of phenothiazines

Spectral Properties. The spectral properties of phenothiazines are described in the literature: NMR [228–230], X-ray diffraction [225], IR spectroscopy [231–233], UV spectroscopy [185], [231], electron spin resonance [234] (and orbital calculations), mass spectrometry [235–237], and coupling of mass spectrometry with chromatography [238].

Analysis. Phenothiazines are mainly separated by chromatography (gas liquid chromatography, high performance liquid chromatography, or thin layer chromatography) [239–242]. Methods of determination are based on chemical properties (redox reactions, complex formation [243]) or spectroscopy (UV absorption, mass spectrometry [244]).

Physical Properties of Products. The physical properties of products mentioned in Chapter 2 are listed in Table 4.

5. Toxicology

Phenothiazines are generally regarded as being well tolerated. The toxicological effects are

largely due to their modes of action, while some specific toxicity phenomena are associated with the chemical properties of the phenothiazine nucleus.

A large number of studies have been carried out on the metabolism of phenothiazines [245–250] and their pharmacokinetics [245]. The phenothiazine nucleus is mainly metabolized by oxidation at the 5- and 7-positions:

Metabolism depends on the nature of the R^2 and R^{10} substituents and, in turn, may also affect the substituents (certain R^2 substituents, but particularly the R^{10} chain [245]).

The toxicity [251], [252] and side effects [253], [254] associated with the mode of action of phenothiazines (Section 2.2) have been investigated in detail [255–257]. Side effects in the CNS are mainly manifested in the extrapyramidal system (Parkinsonism [258], acathesia, delayed dyskinesia [259]) as well as in the dopaminergic [260] and noradrenergic [261] systems.

Effects on fertility have been noted [262], [263]. Mutagenic effects are very slight [264] and no teratotoxicity has been observed [265]. Tolerance problems and interaction with other drugs have been observed but no dependence symptoms [266].

Phenothiazines may cause poor local tolerance [267] or lead to dermal photosensitization [268] and dermatitis on exposure to light [269]. Several other rare effects have been detected [270], [271].

1. Introduction

Phenylenediamine is the common name for diaminobenzene, which exists as three isomers: 1,2-, 1,3-, and 1,4-diaminobenzene. The 1,2-isomer is commonly called *o*-phenylenediamine; the 1,3-isomer is *m*-phenylenediamine; and the 1,4-isomer is *p*-phenylenediamine.

The *toluenediamines*, with six possible isomers, are commonly named by using numbers to designate the position of the amino groups with respect to the toluene methyl group, i.e., 2,3-diaminotoluene or 2,3-toluenediamine (3-methyl-1,2-phenylenediamine) [*2687-25-4*]; 2,4-diaminotoluene or 2,4-toluenediamine (4-methyl-1,3-phenylenediamine) [*95-80-7*]; 2,5-diaminotoluene or 2,5-toluenediamine(2-methyl-1,4-phenylenediamine) [*95-70-5*]; 2,6-diaminotoluene or 2,6-toluenediamine (2-methyl-1,3-phenylenediamine) [*823-40-5*]; 3,4-toluenediamine (4-methyl-1,2-phenylenediamine) [*496-72-0*]; and 3,5-toluenediamine (5-methyl-1,3-phenylenediamine) [*108-71-4*]. An 80 : 20 mixture of the 2,4- and 2,6-isomers is used and sold as *m*-toluenediamine. Commercially available *o*-toluenediamine is a 60 : 40 mixture of the 3,4- and 2,3-isomers.

Like most simple aromatic amines, the phenylene- and toluenediamines can be prepared by electrophilic aromatic nitration, followed by reduction of the introduced nitro group (usually catalytic hydrogenation) to an amino group. This chemistry was developed in the early 1800s. Until the mid-1900s, phenylene- and toluenediamines were used principally for the preparation of dyes, but they are currently more important in the production of high-performance textile fibers, agricultural chemicals, and diisocyanates for the preparation of a variety of polyurethane products.

2. Physical Properties

The melting and boiling points of the phenylene- and toluenediamines are listed in Table 1. All of these compounds are white crystalline solids when pure, except 3,5-toluenediamine which is a liquid at room temperature. They are all readily soluble in hot water and common organic solvents such as alcohols, ketones, and ethers. Because of their limited solubility in cold water, *o*- and *p*-phenylenediamines can be recrystallized from water.

Table 1. Melting and boiling points of phenylene- and toluenediamines

Compound	CAS registry no.	*mp*, °C	*bp*, °C
o-Phenylenediamine	[*95-54-5*]	102 – 103	256 – 258
m-Phenylenediamine	[*108-45-2*]	62 – 63	284 – 287
p-Phenylenediamine	[*106-50-3*]	145 – 147	267
2,3-Toluenediamine	[*2687-25-4*]	63 – 64	255
2,4-Toluenediamine	[*95-80-7*]	97 – 99	283 – 285
2,5-Toluenediamine	[*95-70-5*]	64	273 – 274
2,6-Toluenediamine	[*823-40-5*]	104 – 106	
3,4-Toluenediamine	[*496-72-0*]	91 – 93	265 (sub.) ∗
3,5-Toluenediamine	[*108-71-4*]	>0	283 – 284

∗ sub.=sublimation.

3. Chemical Properties

The chemical properties of the phenylene- and toluenediamines are typical of aromatic amines; they react as bases in aqueous solution and form stable salts with acids. Their most notable chemical characteristic is their ease of oxidation to

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a19_405

complex colored compounds, which is the basis for their use in dyes and hair colorants. Oxidation also occurs if they are stored in the presence of air. The various isomers differ greatly in chemical reactivity due to the relative positions of the two amino groups. Phenylene- and tolueneamines with *ortho* amino groups, for example, readily form heterocyclic compounds, whereas the *m*- and *p*-isomers do not.

The aromatic rings of phenylenediamines can be catalytically hydrogenated to the corresponding diaminocyclohexanes; for example, hydrogenation of *p*-phenylenediamine over a ruthenium on alumina catalyst produces *cis*- and *trans*-1,4-cyclohexanediamine [*15827-56-2*] (cis), [*2615-25-0*] (trans)] in a ratio of 1:3 [1].

***o*-Phenylenediamine.** Benzimidazole [*51-17-2*] is formed by a ring-closure reaction of *o*-phenylenediamine with formic acid. Alkyl-substituted benzimidazoles are obtained by reaction of *o*-phenylenediamine with nitriles or aldehydes in the presence of copper(II) acetate. When *o*-phenylenediamine is reacted with vicinal dicarbonyl compounds, quinoxalines result; reaction with glyoxal [*107-22-2*], for example, gives quinoxaline [*91-19-0*]. Benzotriazole [*95-14-7*] is obtained by the reaction of *o*-phenylenediamine with nitrous acid in dilute sulfuric acid [2].

The oxidation of *o*-phenylenediamine with aqueous iron(III) chloride produces 2,3-diaminophenazine [*655-86-7*]; oxidation with silver oxide in diethyl ether gives *o*-benzoquinonediimine [*4710-40-1*]; and oxidation with air in a solution of copper(I) chloride in pyridine is reported to give 1,4-dicyano-1,3-butadiene [*821-60-3*] [3].

***m*-Phenylenediamine** can be readily acylated with acid chlorides to form substituted amides. With diacid chlorides it forms polyamides; for example, with isophthaloyl chloride a poly(*m*-phenyleneisophthalamide) [*24938-60-1*] is produced, which is the starting material for textile fibers. When *m*-phenylenediamine is reacted with excess nitrous acid, both amino groups are diazotized and couple with unreacted *m*-phenylenediamine to give 5,5′-[(4-methyl-*m*-phenylene)bisazo]bis(toluene-2,4-diamine), Bismarck Brown, one of the first azo dyes.

***p*-Phenylenediamine** is more readily oxidized than the *o*- or *m*-isomer. Acidic manganese dioxide or potassium dichromate produces 1,4-benzoquinone [*106-51-4*]. When *p*-phenylenediamine is oxidized with hydrogen peroxide, for example in a hair dye, the first product is *p*-benzoquinonediimine [*4377-73-5*], which can react with unreacted *p*-phenylenediamine to form a brown dye known as Bandrowsky Base [*20048-27-5*]. The diimine will also react rapidly with other aromatic amines and phenols to form a variety of colorants.

The amino groups of *p*-phenylenediamine undergo reactions typical of aromatic amines, (e.g., diazotization, acylation, alkylation, and phosgenation).

The chemical properties of the toluenediamines are identical to those of the phenylenediamines, i.e., the same type of compounds can be made from them. The methyl group may slow down the reaction rate of an adjacent amine group due to steric hindrance, but this effect is minor in most cases.

4. Production

Preparation of phenylene- and toluenediamines almost always starts with aromatic nitration followed by reduction, although some exceptions exist. The initial starting material in most cases is either benzene or toluene.

o-Phenylenediamine. The principal route to *o*-phenylenediamine is by the reduction of 2-nitroaniline [*88-74-4*], which is produced by the amination of 2-chloronitrobenzene [*88-73-3*] with ammonia [4]. Hydrogenation can be achieved with a variety of reducing agents, such as iron powder [5], hydrazine [6], or hydrogen sulfide [7], but commercially it is performed catalytically in the liquid phase over a palladium catalyst [8], [9]. Other routes to *o*-phenylenediamine include the amination of 1,2-dichlorobenzene [*95-50-1*] with ammonia [10], [11] and the direct amination of aniline [12]. The yield in the latter process is, however, low. A method starting from cyclohexane, sulfur, and ammonia has also been described [13].

m-Phenylenediamine. The *m*-isomer is synthesized by catalytic hydrogenation of 1,3-dinitrobenzene [*99-65-0*], which is obtained as the principal product in the dinitration of benzene with a mixture of sulfuric and nitric acids [14–16]. A certain amount of *o*- and *p*-phenylenediamines (about 10 %) are also produced as byproducts, but these can be removed by chemical treatment of the crude nitration product either prior to hydrogenation [17] or during isolation of the *m*-diamine by distillation. Hydrogenation is usually performed in water or methanol over a supported palladium or Raney nickel catalyst [18], [19].

p-Phenylenediamine. Routes to *p*-phenylenediamine include reaction of 1,4-dichlorobenzene [*106-46-7*] [10], [11], hydroquinone [*123-31-9*], [20], [21], or aniline [*62-53-3*] [22] with ammonia; hydrogenation of 4-nitroaniline [*100-01-6*] [23]; Hoffmann degradation of terephthalamide [*3010-82-0*] [24]; and diazotization of aniline to a triazine followed by rearrangement [25], [26].

The most important commercial routes are the catalytic hydrogenation of 4-nitroaniline and aniline diazotization. The *4-nitroaniline route* is identical to the preparative method for the *o*-isomer; 4-chloronitrobenzene is aminated with ammonia to the nitroaniline, followed by hydrogenation over a palladium catalyst. A disadvantage of this process is the 65 : 35 *ortho – para* ratio obtained during nitration of chlorobenzene because of the difficulty of matching the demand for the fixed ratio of isomers. The diazotization process used by Du Pont in the United States, overcomes this problem because it is based only on aniline.

In the *Du Pont process*, aniline is diazotized using nitrogen oxides [25]. The diazo compound reacts with excess aniline to produce 1,3-diphenyltriazine [*136-35-6*], which rearranges under acidic conditions to 4-aminoazobenzene [*60-09-3*]. 4-Aminoazobenzene is catalytically cleaved and hydrogenated to give *p*-phenylenediamine and aniline. The aniline is recovered and recycled.

One route to *p*-phenylenediamine that does not involve any nitration and does not start with benzene is the *Akzo process*, which can start with dimethyl terephthalate [*120-61-6*] or waste poly(ethylene terephthalate). Either ester can be reacted with ammonia to produce terephthalamide. The diamide is chlorinated to give a chloroamide that is then reacted with a base such as sodium hydroxide to produce *p*-phenylenediamine (Hoffmann degradation) [24].

Toluenediamines. From a commercial standpoint, the most important toluenediamine isomers are the *meta*, or 2,4- and 2,6-isomers, which are obtained as a mixture by hydrogenation of the corresponding dinitrotoluenes. The processes involved are similar to those used for the manufacture of *m*-phenylenediamine, but using toluene as the starting material instead of benzene. About 4 % of the 2,3- and 3,4-isomers are formed as byproducts during toluene dinitration, and the same isomeric diamines subsequently appear as impurities in the mixture of *m*-diamines. They can be removed by distillation and are sold as commercial *o*-toluenediamine.

Table 2. Phenylenediamine product specifications

	Isomer		
	Ortho	*Meta*	*Para*
Water, % (min.)	0.2	0.1	0.1
fp, °C	2.7		
Purity, %	99.5	99.8	99.5
Content *ortho* isomer, ppm		200	1000
Meta isomer, ppm	1 ∗		1000
Para isomer, ppm	1 ∗	100

Nitrobodies as dinitrobenzene, %		0.1	
Aniline, ppm			500

∗ Combined *meta* and *para* content = 0.25 %.

5. Environmental Protection

Aquatic Toxicity. The LC_{50} of *o*-phenylenediamine determined with fathead minnows is 44 mg/L (96 h exposure). For the *p*-isomer it is only 0.028 mg/L, which indicates that *p*-phenylenediamine is very toxic to aquatic life. The LC_{50} of the *m*-isomer is greater than 1 mg/L but less than 50 mg/L [27–29]. The LC_{50} for toluenediamine is 430 mg/L for golden shiners and 1000 mg/L for minnows [30].

6. Quality Specifications

All three *phenylenediamine isomers* are available commercially as flaked solids; the *m*-isomer

is also available as cast solid and molten liquid. The commmercial products are light tan to brown in color. They tend to discolor during storage, and the presence of air, moisture, or elevated temperature hastens color deterioration. However, color alone is not a good criterion of purity because highly colored material may still be above the minimum purity specifications. Typical sales specifications are shown in Table 2.

Toluenediamines are available as cast solids in drums and molten liquids in tank cars. The solid *m*-isomer mixture is yellow to tan, whereas the *o*-mixture is light gray to purple. Like the phenylenediamines, these compounds tend to darken on storage. Product specifications are shown in Table 3.

Table 3. Toluenediamine product specifications

	Isomer	
	Ortho	*Meta*
Purity, % (min.)	97.0	99.0
Normalized isomer ratio, wt %		
2,4-		79 – 81
2,6-		19 – 21
o-	99.5 (min.)	
Other	0.5 (max.)	
Ortho isomers (2,3- and 3,4-)		0.3 (max.)
Para and *meta* isomers (2,5- and 3,5-)		1.0 (max.)
Nitrobodies as dinitrotoluene, %		0.03 (max.)
Moisture, %	1.0 (max.)	0.1 (max.)
Toluidines, %		0.05 (max.)

7. Storage and Transportation

All aromatic diamines should be stored in tightly closed, upright containers in a cool, well-ventilated area away from heat and sources of ignition.

In the United States, the shipping of *o*-phenylenediamine other than by air (DOT) is not regulated. *m*-Phenylenediamine and *p*-phenylenediamine are shipped under hazard class ORM-A and UN no. 1673. For international shipping (IMO) by water or air, all three isomers are shipped under the name phenylenediamine and hazard class Poison β, 6.1.

8. Uses

For about a hundred years, phenylene- and toluenediamines were used mainly in the manufacture of dyes and dye intermediates. However, in the mid-1900s these compounds became very important starting materials for a variety of polymers, which now accounts for most of their consumption.

o-Phenylenediamine. A significant proportion of *o*-phenylenediamine is used for the preparation of benzimidazole-derived agricultural fungicides such as benomyl [*17804-35-2*]. This is produced in the United States by Du Pont and sold under the trade name Benlate, and in the former Soviet Union under the name Uzgen. Other fungicides made from *o*-phenylenediamine include thiophanate methyl (Topsin), a turf fungicide made by Nippon Soda for sale by others, and fuberidazole produced by Bayer.

A small but high-value use of *o*-phenylenediamine is in the preparation of a variety of substituted benzimidazoles used as veterinarian anthelmintics. These compounds are available under trade names such as Equizole (thiabendazole) (Merck, Sharpe & Dohme) and Panacur (fenbendazole) (Hoechst), [31].

Benzotriazole and tolyltriazole are prepared, respectively, from *o*-phenylenediamine and an isomeric mixture of *o*-toluenediamines, by reaction with nitrous acid. These compounds are widely used as corrosion inhibitors in automobile antifreezes and other aqueous solutions because of their specific inhibition of copper and copper alloys.

Mercaptobenzimidazole [*583-39-1*] obtained from *o*-phenylenediamine and potassium ethyl xanthate is used as an antioxidant for rubber (Antioxidant MB, Mobay). A substituted benzotriazole derived from *o*-phenylenediamine is sold by Ciba – Geigy under the trade name Tinuvin P as an ultraviolet light absorber for stabilizing plastics and other organic materials against discoloration and deterioration [32].

m-Phenylenediamine. The fastest growing use for *m*-phenylenediamine is in the production of the aramid fiber poly(*m*-phenyleneisophthalamide), which is obtained by reaction of *m*-phenylenediamine with isophthaloyl chloride [*99-63-8*] [33]. This material is used in areas where high-temperature resistance or fire retardancy is required. Examples are protective clothing and aircraft interiors. The polymer is made in the United States by Du Pont (Nomex), in Japan

by Teijin, and in the former Soviet Union. *m*-Phenylenediamine is also used for curing epoxy resins to impart high-temperature strength and good resistance to chemical solvents. Such cured resins are used in filament-wound casings and adhesives.

m-Phenylenediamine is still used as the starting material for many dyes. Examples include Basic Brown 1 (Bismarck Brown), Basic Orange 2, Direct Black 38, and Developed Black BH.

p-Phenylenediamine. Aramid textile fibers are obtained from poly(*p*-phenylene terephthalamide) [*24938-64-5*], which is produced by the reaction of *p*-phenylenediamine with terephthaloyl chloride [*100-20-9*] [33–35]; the two suppliers are Du Pont (Kevlar) and Akzo (Twaron). These fibers are used for reinforcing tires and V-belts, as a substitute for asbestos in brake linings, in reinforcing plastics for aerospace and sporting applications, and for a variety of other uses where high strength and tensile modulus are required [36].

Reaction of *p*-phenylenediamine with phosgene produces *p*-phenylene diisocyanate (PPDI), a symmetrical diisocyanate that gives highly crystalline polyurethanes reported to have good high temperature properties as both thermoplastics and cast elastomers [37].

p-Phenylenediamine is still employed in hair dyes and is the main component of oxidation hair dyes. *N,N′*-disubstituted *p*-phenylenediamines are used extensively as photographic chemicals, as fuel additives, and in the compounding of rubber. However, most of these compounds are made by the reductive alkylation of *p*-nitroaniline rather than from the parent diamine.

Toluenediamines. The largest use for toluenediamines is in the production of diisocyanates for the polyurethane industry. These diisocyanates are synthesized by reaction of *m*-toluenediamine (80 : 20 mixture of the 2,4- and 2,6-isomers) with phosgene. The resulting diisocyanates (trade name TDI) are used principally in polyurethanes as flexible foams for upholstery and other types of padding.

9. Toxicology and Occupational Health

All aromatic diamines are toxic when ingested and may cause skin and eye irritation. In some individuals, inhalation can lead to respiratory problems and asthma. Thus, as a class these diamines should be treated as very hazardous materials, and all contact with the body should be avoided by use of appropriate protective equipment.

***o*-Phenylenediamine.** In addition to causing skin rashes, evidence exists that *o*-phenylenediamine can permeate the skin in toxic amounts. A single application to the skin of rabbits produced weight loss, loss of coordination, weakness, darkening of the urine, and death. Currently, this compound is not considered a carcinogen, but it produces noninheritable genetic damage in bacterial and mammalian cell cultures [27].

***m*-Phenylenediamine.** The toxic effects observed in animals from short exposure to *m*-phenylenediamine by inhalation, ingestion, or skin contact include liver and kidney damage. Since no carcinogenic activity has been noted in animal tests, *m*-phenylenediamine is not considered a carcinogen, although it is mutagenic in bacterial cultures and may have embryotoxic activity [28].

***p*-Phenylenediamine.** Toxic effects observed in animals from single exposures to *p*-phenylenediamine by inhalation include tremors, cyanosis, and severe weight loss. Toxic effects by ingestion include weight loss and lethargy. This compound does not have carcinogenic effects on animals. Tests for reproductive activity have not yet been performed [29].

p-Phenylenediamine is such a strong dye-former in the presence of air and moisture that everything in contact with it, whether skin, clothes, or walls, is almost immediately dyed a dark blueish black. Thus, exposure to *p*-phenylenediamine in even small amounts or lack of good industrial hygiene in operations that involve its use can be readily detected.

***o*-Toluenediamines.** The toxic inhalation and ingestion effects of the commercial mixture of *o*-toluenediamines can be assumed to be similar to those of phenylenediamines, but they do not appear to be primary skin irritants. The Ames mutagenic assay of *o*-toluenediamines is positive. Because the mixture can contain up to 0.5 %

of the *meta* isomers, the toxic effects of these compounds must be considered when working with commercial *o*-toluenediamine.

***m*-Toluenediamine.** Application of *m*-toluenediamine to the skin in hair dyes does not appear to produce toxic or carcinogenic effects [38], but it does appear to be a carcinogen when ingested by rats [39]. It is an active mutagen in the Ames test.

1. Introduction

Phosgene [*75-44-5*], $COCl_2$, (carbonic acid dichloride, carbonyl chloride), M_r 98.82, was discovered in 1812 by J. Davy from the action of sunlight on a mixture of carbon monoxide and chlorine. The name phosgene is derived from the Greek words for "light" and "generate". Phosgene is a colorless gas, which condenses under normal pressure at 7.56 °C to form a colorless liquid.

The importance of phosgene, apart from its use as a warfare agent in World War I [1], was initially its various uses in the production of intermediates in many different fields of chemistry. Currently, now that the polyurethane plastics have become accepted, most phosgene produced is used in the manufacture of diisocyanates.

Because of its high toxicity and wide range of commercial applications, exceptional effort has been devoted worldwide to the safe handling of phosgene. This high level of safety technology is being developed further. To avoid safety problems, costly work has been performed to develop phosgene-free processes for isocyanate production. Up to now, however, these have gained only partial acceptance on the commercial scale (see Chap. 8).

2. Properties

2.1. Physical Properties

Important physical properties of phosgene may be summarized as follows:

mp	−127.8 °C
bp (101.3 kPa)	7.56 °C
Critical data	
Critical pressure	5.674 MPa
Critical temperature	182 °C
Critical density	0.52 g/cm^3
Density at 20 °C	1.38 g/cm^3
Surface tension	
at 16.7 °C	2.11×10^{-2} N/m
at 34.5 °C	1.76×10^{-2} N/m
at 46.1 °C	1.59×10^{-2} N/m
Specific heat	
Gas at 25 °C	6.17 J kg^{-1} K^{-1}
Liquid at 7.5 °C	1026 J kg^{-1} K^{-1}
Enthalpy of formation at 25 °C	
from the elements	− 220 kJ/mol
from CO and Cl_2	− 107.6 kJ/mol
Heat of evaporation	
at *bp*	24.2 kJ/mol
Heat of fusion	5.740 kJ/mol
Ebullioscopic constant	29

The phosgene molecule is planar, with atomic distances of 1.166×10^{-10} m for C – O and 1.746×10^{-10} m for C – Cl. The Cl – C – Cl bond angle of 111.3° is close to the tetrahedral angle (method of determination: microwave spectroscopy [2]).

Phosgene is readily soluble in many organic solvents and itself dissolves many organic substances. The only inorganic substances which

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a19_411

it dissolves are the halogens and a few halides ($AlCl_3$, $SbCl_3$, $SbCl_5$) [3]. Activated carbon adsorbs large amounts of phosgene.

Vapor pressure and density of phosgene are given in Table 1 [4]. The following properties are compiled in graphs over fairly wide temperature ranges in [5]: vapor pressure, heat of vaporization, specific heat, density, viscosity, surface tension, and thermal conductivity. Spectra of phosgene are given in the following references: IR spectra [6], [7]; UV spectra [8]; Raman spectra [6], [9]; photoelectron spectra [10].

Table 1. Vapor pressure and density of liquid and gaseous phosgene according to [4]

ϑ, °C	p, MPa	ϱ_L, g/cm^3	ϱ_G, g/cm^3
10	0.109	1.405	0.005
50	0.404	1.306	0.016
100	1.38	1.165	0.046
150	3.49	0.966	0.142

2.2. Chemical Properties

Dissociation of phosgene to carbon monoxide and chlorine is noticeable at 200 °C and practically complete at 800 °C. At 300 °C it is about 5 %, and at 400 °C about 20 % (for further values, see [11]). The temperature dependence of the equilibrium constant of the dissociation reaction and other thermodynamic functions are given in [12].

A survey of the reactions of phosgene is given in [13]. Literature sources cited there are repeated here only if they are survey articles.

In order to avoid the difficulties associated with the toxicity of phosgene, substitutes for phosgene can sometimes be used in the laboratory e.g., trichloromethyl chloroformate ("diphosgene") [14–17] and bis(trichloromethyl) carbonate ("triphosgene") [18].

2.2.1. Reactions with Organic Compounds

Being the dichloride of carbonic acid, phosgene is very reactive and reacts with many other substances to form a wealth of products, which are usually also very reactive. The importance of phosgene for the production of synthetic intermediates is based on the large number of possible coreactants.

The reaction with *primary amines* is by far the most important reaction of phosgene, which made it become a large-scale product of the chemical industry. The first step is the formation of carbamoyl chlorides, from which isocyanates are formed by elimination of HCl at elevated temperature:

$$R-NH_2 \xrightarrow[-HCl]{COCl_2} R-NH-COCl \xrightarrow[-HCl]{} R-NCO$$

This scheme is used in the production of the isocyanates used for intermediates and pesticides (→ Isocyanates, Organic, Chap. 4.1.) and of all diisocyanates important for polyurethane chemistry, such as toluene diisocyanate [*1321-38-6*] and methylenediphenyl diisocyanate monomer [*101-68-8*] and polymer [*9016-87-9*] [19]. Aromatic *ortho*-diisocyanates can also be obtained via intermediate formation of the corresponding benzimidazolone [20]:

With *secondary amines*, phosgene forms the fairly stable *N, N* - dialkylcarbamoyl chlorides:

$$R_2NH \xrightarrow[-HCl]{COCl_2} R_2N-COCl$$

Secondary amides react with phosgene to form imidoyl chlorides, which are of preparative importance because of their reactivity:

$$RCONHR^1 \xrightarrow[-HCl,\ -CO_2]{COCl_2} R-\overset{\overset{Cl}{|}}{C}=NR^1$$

Tertiary amines add to phosgene in the cold to form cationic complexes, which eliminate alkyl chlorides upon heating:

$$R_3N \xrightarrow{COCl_2} [R_3NCOCl]^+Cl^- \longrightarrow R_2NCOCl + RCl$$

With excess tertiary amine, tetrasubstituted ureas are formed in excellent yields:

$$2\,R_3N \xrightarrow{COCl_2} R_2N-CO-NR_2 + 2\,RCl$$

Nitriles react with phosgene to form heterocyclic compounds with the parent ring systems

of isoquinoline, pyrimidine, and triazine (cf. also [21]).

Phosgene reacts fairly rapidly with *alcohols,* and more slowly with *phenols*, to form chloroformic esters (→ Chloroformic Esters, Chap. 4.). This reaction is of considerable industrial importance (a survey is given in [22]). The reaction is usually carried out in the presence of acid acceptors such as amines or inorganic hydroxides. It can also be accelerated catalytically (with *N, N*-dialkylamides or quaternary ammonium salts as catalysts).

$$\mathrm{ROH} \xrightarrow[-\mathrm{HCl}]{\mathrm{COCl_2}} \mathrm{RO-COCl}$$

Carboxylic acids react with phosgene to form acid chlorides in the presence of catalysts such as *N*, *N*-dialkylcarbamides or tertiary amines.

Figure 1. Simplified flow sheet for the production of phosgene
a) Reaction; b) Recooling of the coolants; c) Phosgene liquefaction; d) Phosgene absorption

2.2.2. Reactions with Inorganic Compounds

Phosgene reacts slowly with *water* in the cold, but more rapidly when hot to yield carbon dioxide and hydrochloric acid. The reaction is accelerated by acids [23–30].

Ammonia reacts with phosgene to form urea and ammonium chloride.

A large number of *metallic oxides* are converted by phosgene to their chlorides at elevated temperatures. This reaction is commercially important for the production of aluminum chloride (→ Aluminum Compounds, Inorganic, Chap. 4.1.2.).

Compounds analogous to phosgene are obtained by reaction of phosgene with certain *halides*; carbonyl fluoride is formed with nitrogen trifluoride (NF_3), carbonyl bromide with aluminum bromide, and " carbonyl isocyanate" in a salt melt with potassium isocyanate [31]:

$$\mathrm{COCl_2 + 2KNCO} \xrightarrow{400\,^\circ\mathrm{C}} \mathrm{O{=}C(NCO)_2 + 2KCl}$$

Phosgene reacts with calcium fluoride at 500 °C to form fluoromethane and the various fluorochloromethanes.

3. Production

Phosgene is obtained commercially by passing carbon monoxide and chlorine over activated carbon. The enthalpy of formation is −107.6 kJ/mol, i.e., the reaction is strongly exothermic (for the kinetics of catalytic phosgene formation, see [32], [33]). Carbon monoxide is added in stoichiometric excess to keep the free chlorine content of the phosgene as low as possible, since chlorine can lead to the formation of undesirable products during further processing.

Process Description. The reaction is carried out in a multitubular reactor of carbon or stainless steel, whose tubes are filled with the granulated catalyst (particle size 3 – 5 mm). The tube diameter is 50 – 70 mm. The temperature of the activated carbon bed is up to ca. 400 °C in the very lowest region of the tubes, but it then falls rapidly along the tubes to product temperatures of 40 – 150 °C.

The heat of reaction is dissipated by water or an organic heat - carrier in the shell of the reactor. A flow sheet of the production process is given in Figure 1.

In a variant, high-boiling cooling liquids (*bp* ca. 200 – 300 °C) are used as coolants by the evaporative cooling principle. The vapors of these heat carriers are condensed with water, which is then vaporized in turn and used in this form as a heating medium, e.g., in other plants. Since the carbon monoxide – chlorine conversion is incomplete at the high reaction temperatures the reaction product is subsequently led through conventional reactors [34].

The reaction is carried out under normal pressure or slight excess pressure. The gaseous phos-

gene is obtained at a temperature of 40 – 150 °C. It is either processed directly, or condensed with water or a coolant. Noncondensable parts of phosgene are absorbed directly with solvent beforehand to form phosgene solution. Nonabsorbable gaseous components (inert gas, CO, phosgene) are fed to waste-gas treatment (see Chap. 6). The activated carbon catalyst can have a service life of up to several years. The service life depends on the purity of carbon monoxide.

Chlorine is usually produced from chlor – alkali electrolysis and HCl electrolysis or from evaporators in which liquid chlorine is evaporated. Usually chlorine is fed through a preheater before mixing with carbon monoxide in order to avoid introducing liquid chlorine into the phosgene generator.

Carbon monoxide is usually produced from natural gas or naphtha in steam reforming plants, but also partly from coke, from which it is obtained by reaction with CO_2 and oxygen. Interfering byproducts are methane and hydrogen in CO from the reformer, and sulfur compounds and hydrogen (from the water content of the coke) in CO from coke. The content of methane and hydrogen is of great importance for safety, because it can lead to spontaneous exothermic HCl formation on mixing with CO and chlorine. The temperature rise associated with this involves the risk of reaction of chlorine with the pipe material (chlorine – iron fire). The presence of sulfur compounds (e.g., COS, $CSCl_2$) can lead to deterioration in the quality of the resulting products during the further use of the phosgene.

Phosgene can be formed at high temperatures from chlorinated hydrocarbons with atmospheric oxygen. This reaction can lead to possible health hazards, above all in welding technology [35–38].

4. Storage and Transportation

Storage and transportation of phosgene are avoided as far as possible for safety reasons. Generally, only the minimum amounts necessary in the course of the process are stored at intermediate stages. Steel vessels are suitable containers if corrosive impurities, especially water, can be excluded. Phosgene is shipped almost exclusively on the kilogram scale in seamless drawn steel cylinders or in pressure drums which are regularly checked at specific intervals.

Transport classifications for phosgene are as follows:

IMDG Code (GGVSee)	Class 2 D 2227
	E-F 2106
Emergency Schedule (EmS)	2-08
Medical First Aid Guide for Use in Accidents Involving Dangerous Goods (MFAG)	600
RID (GGVE)	Class 2 Rn 201 no. 3at
ADR (GGVS)	Class 2 Rn 2201 no. 3at
ADNR	Class 2 Rn 6201 no. 3at
EC Directive	No. 006-002-00-8
USA CFR 49	§ 172.101 Poison A
ICAO/IATA-DGR	Class 2
UN no.	1076 forbidden

5. Quality and Analysis

The phosgene obtained from production in the presence of activated carbon is so pure that an additional purification step is usually unnecessary. Possible impurities are e.g., free chlorine, iron chloride, carbon tetrachloride, polychlorinated hydrocarbons, hydrogen chloride, and sulfur compounds. Phosgene can be purified by distillation when required.

The quality of phosgene (liquid or in concentrated solution) can be determined by the following methods:

1) By gas chromatography [39]
2) By IR spectroscopy [40]
3) By titration. Iodine is liberated from a NaI – acetone solution by phosgene and from an aqueous NaI solution by chlorine which may be present as an impurity. The iodine is then titrated with thiosulfate. Other possible impurities are determined as follows: $FeCl_3$ is determined by reacting the sample with potassium iodide solution after pretreatment. Hydrogen chloride is determined by titration with NaOH [41].
4) Total chlorine is determined as chloride after saponification with NaOH. Separate determination is possible of *free chlorine*; e.g., by evaporation of the phosgene, absorption

in a solution of arsenious acid, and back-titration with iodine solution; and *free HCl* by Liebig titration of the hydrogen cyanide released from mercury(II) cyanide.

5) Phosgene can be reacted with an aniline–toluene solution to form diphenylurea which can then be determined qualitatively and quantitatively [42].

For the determination of phosgene in gaseous mixtures see Chapter 6.

6. Waste-Gas Treatment and Monitoring

The residual gases from phosgene production and the off-gases from plants for phosgene processing must be freed from phosgene in a decomposition unit. This is achieved by various methods:

Decomposition with Alkaline Scrubbing Agents, mainly Sodium Hydroxide Solution. The residual gas is led through packed towers, at the top of which sodium hydroxide solution is introduced. Make-up sodium hydroxide solution is added under pH control. Venturi scrubbers can also be used.

Decomposition in Activated Carbon Towers. The residual gas is passed through towers that are filled with activated carbon and fed with water. Water and residual gas are usually fed cocurrently to avoid flooding of the packing. The water is usually recycled. If the concentration of hydrochloric acid which is formed by decomposition of phosgene exceeds 10 %, the decomposition effect is greatly reduced. Therefore a sufficient supply of fresh water must be assured [43]. For safety reasons frequently two towers in series are used.

Combustion. The residual gases are burnt so as to convert phosgene to CO_2 and HCl only. An advantage of this method is that all remaining pollutants in the residual gas, such as solvents and carbon monoxide, are burnt together with phosgene [44].

Normally, the outlet gas from the phosgene destruction equipment is continuously monitored for residual phosgene content. The following methods of detection are used:

1) Gas detectors with test tubes [45]
2) Photometric methods: (1) IR spectrometry, preferably for waste-gas monitoring in the concentration ranges 0 – 100 and 0 – 1000 mL/m^3 [46], [47]. (2) Devices whose measuring principle is based on the colorimetric evaluation of the Dixon and Hands [48] color reaction [49–52]. The measuring ranges are 0 –250 µL/m^3 and 0 – 100 µL/m^3. These devices are also used for room air monitoring.
3) Ionization methods [53], [54]
4) Gas chromatography [39]
5) Electrochemical methods [55], for use in the range of 0 – 300 µL/m^3

Methods in development will permit line and area monitoring ("fence line monitoring") in the area around phosgene plants using Fourier Transform IR spectrometry (FTIR) [50], [56].

7. Safety Precautions

When handling phosgene, extensive safety precautions are required to prevent exposure to phosgene. These measures can be divided into

1) Primary technical measures
2) Secondary technical measures
3) Organizational measures
4) Personal precautions

Primary Technical Measures. The primary technical measures are aimed at preventing phosgene emission from the closed equipment. This is achieved by e.g., selection of resistant, high-grade materials for equipment and lines; careful testing of this equipment and lines, especially the welds; leak tests before resuming operation of plant units; the use of pumps which are hermetically sealed to the outside (canned motor pumps, magnetic pumps); the use of high-grade materials for flange gaskets; and regular inspections of equipment and lines. In the field of process control engineering, particularly high requirements are set for the quality and design of process control equipment. Plant equipment which are particularly important for safety have duplicated process control instrumentation. Automatic systems ensure immediate safe shutdown of the plant when important process parameters move outside a narrow bandwidth. In addition, the probability of phosgene emission

and the emission potential are reduced further by continual optimization of the process system. In this way, e.g., the number of vessels containing phosgene and their phosgene content are reduced.

Secondary Technical Measures. Secondary technical measures are used to detect leaks as soon as possible and to combat escaped phosgene. These measures include, e.g., continuously operating alarm systems for monitoring room air and ambient air, systems for combating escaped phosgene by chemical reaction (e.g., steam – ammonia curtains in the case of gaseous emissions), jacketed pipes, and complete containments for phosgene processing plants or plant units. Leaks of liquid phosgene or phosgene solution can effectively be combated by covering the phosgene-containing liquid with sorption and destruction agents.

Organizational Measures. The organizational measures ensure that the staff operate the plants safely and initiate rapid countermeasures following malfunctions or the detection of leaks. These measures include special training, routine plant inspection, training for exceptional situations, clear operating instructions, and regular safety discussions.

Personal Safety Precautions. The personal safety precautions ensure that the staff are protected from exposure during a possible release of phosgene into the atmosphere and that a possible exposure is detected early enough to prevent inhalation of a dose which would be dangerous to health. The staff are therefore equipped with escape masks or respirators. For other personal safety precautions see section 10.

8. Uses

Its many different reactions makes phosgene an important starting compound in the production of intermediates and end products in many branches of large-scale industrial chemistry.

Diisocyanates. Most phosgene is used for the production of diisocyanates as starting materials of polyurethane chemistry. The most important compounds are toluene diisocyanate (TDI) [*1321-38-6*] as well as monomeric [*101-68-8*] (MDI) and polymeric methylenediphenyl diisocyanate [*9016-87-9*] (PMDI) (→ Isocyanates, Organic, Chap. 3.).

The production of *toluene diisocyanate* (TDI) starts from toluene, which is converted in a continuous process to a mixture of 2,4- and 2,6-dinitrotoluene. This mixture is hydrogenated with hydrogen to give 2,4- and 2,6-toluenediamine (TDA). The reaction with phosgene is usually carried out in a continuous process, using e.g., toluene, chlorobenzene, or 1,2-dichlorobenzene as solvents, at 65 – 180 °C and at excess pressure. In the course of this process hydrogen chloride (reaction product), phosgene (excess reactant), and finally the solvent are successively separated. The end product TDI is purified by distillation.

For the production of *methylenediphenyl diisocyanate* (MDI), aniline is used as the starting material. It is condensed with formaldehyde to form a mixture of isomeric methylenediphenyldiamines (MDA). The subsequent reaction of this amine mixture with phosgene is similar to that described above for TDI. The end product is a mixture of isomeric MDI and various PMDI types. Distillative purification is not carried out.

$n = 0$ MDI
$n > 0$ PMDI

The high toxicity of phosgene has resulted in intensive work on the development of phosgene-free processes for diisocyanate manufacture. These processes start from the corresponding dinitro compounds, which react with CO to form diisocyanates [57–62]. The reaction of the amines with compounds other than phosgene such as dimethyl carbonate [63] or methanol and carbon monoxide with oxygen [64], is another line of development. The development of phosgene-free processes has been successful for only a few aliphatic diisocyanates; the production of other diisocyanates by this route suffers from a lack of profitability or process engineering difficulties (→ Isocyanates, Organic, Chap. 4.3.) [65], [66].

Aliphatic diisocyanates are important starting materials for polyurethanes used in coatings. Monoisocyanates, such as isopropyl isocyanate, phenyl isocyanate, and chlorophenyl

isocyanates, are important intermediates in the manufacture of herbicides and insecticides.

Polycarbonates. The next largest phosgene consumers are polycarbonate plastics (→ Polycarbonates). They are produced by reaction of 2,2-bis(4-hydroxyphenyl)propane (bisphenol A) with phosgene, either directly or indirectly via diphenyl carbonate.

Chloroformic Esters. The reaction of phosgene with alcohols to form chloroformic esters is very important for industrial applications. These esters are exceptionally versatile intermediates, e.g., for the production of carbonic esters, polycarbonates, and polyurethanes, and for many other applications (→ Chloroformic Esters).

Urea Azo Dyes. The treatment of aminoazo dyes with phosgene in aqueous solution to produce symmetrical urea azo dyes, has been practiced since the end of the 19th century (→ Azo Dyes, Chap. 4.1.6.).

Carbonate Esters. Among the carbonate esters, dimethyl and diethyl carbonates in particular are used in the pharmaceutical industry and in the production of pesticides. Diphenyl carbonate is an intermediate in the production of polycarbonates.

Friedel – Crafts Acylations. Friedel – Crafts acylations with phosgene are important reactions, e.g., for the dye industry, yielding important ketones such as benzophenone (→ Ketones, Chap. 7.3.) or 4,4′-bis(dimethylamino)benzophenone (Michler's ketone) (→ Acylation and Alkylation, Chap. 2.2.). Benzoyl chloride can also be obtained in this way from benzene. The production of 2,5-dichlorobenzoic acid from 1,4-dichlorobenzene and phosgene in an $AlCl_3$ – sodium formate melt is described in [67].

Other Uses. Phosgene undergoes commercially important cyclization reactions with aminocarboxylic acids, aminophenols, and diamines. Acid chlorides are often prepared by reaction of carboxylic acids with phosgene (for suitable catalysts see [68]). Examples are the production of isophthaloyl dichloride and terephthaloyl dichloride on the large industrial scale.

Phosgene disproportionates to form carbon tetrachloride and carbon dioxide at high temperatures (→ Chlorinated Hydrocarbons).

In *inorganic chemistry*, phosgene is used as an intermediate for the large-scale production of aluminum chloride (→ Aluminum Compounds, Inorganic, Chap. 4.1.2.). The production of zirconium chloride is described in [69].

9. Economic Aspects

In 1989 the estimated world production of phosgene was 2.74×10^6 t. This was divided between fields of application approximately as follows (figures in 10^6 t):

TDI	1.18
MDI	0.96
Polycarbonate	0.30
Aliphatic diisocyanates	0.10
Monoisocyanates	0.05
Chloroformic esters	0.05
Other fields of application	0.10

The main producers of phosgene are identical with the large TDI and MDI manufacturers. In the United States these are Dow, Mobay (Bayer), Rubicon (ICI), BASF, and Olin, and in Western Europe Bayer, BASF, Dow, ICI, Rhône-Poulenc and Montedipe. About 40 % of the world production of phosgene is manufactured in Western Europe, ca. 37 % in the United States, ca. 11 % in Japan, and ca. 7 % in Eastern Europe. Latin America and the Far East (excluding Japan) make up the remaining 5 %. The growth rate of production largely corresponds to the growth rate of TDI and MDI production and is estimated at 4 % per year for the 1990s.

10. Toxicology and Occupational Health

Phosgene is a typical lung irritant gas without generalized systemic absorption. Because of its low water solubility, phosgene reacts only to an insignificant extent with the aqueous film on the mucous membranes of the upper respiratory tract. Most of the inhaled phosgene reaches the pulmonary alveoli, where gas exchange occurs. Here the phosgene reacts with NH_2, OH, and SH groups of the blood – air barrier [70]:

In the course of this, nucleic acid bases and enzymes are modified and the blood – air barrier loses its function as a membrane between the blood vessels and the pulmonary alveoli. As a result, blood plasma is able to pass from the blood vessels into the pulmonary alveoli (lung edema) thereby increasingly disturbing the gas exchange. Death can result from "internal suffocation".

In the very rare cases of inhalation of extremely high doses of phosgene, unreacted phosgene may penetrate the blood – air barrier, reach the blood vessels, and react with blood constituents. Red blood cells break down and the fragments block up the lung capillaries. The cessation of capillary circulation can lead to death within a few minutes [71].

The clinical picture of phosgene poisoning varies according to the inhaled concentration or dose [71], [72]. Death by heart failure due to blockade of the pulmonary circulation can occur within a few minutes after inhaling excessively high doses. Typically, however, medium-size doses are inhaled, and the poisoning then follows a prolonged course. Characteristic is a clinically silent "latency phase" in which the liquid gradually accumulates in the lungs until finally signs and symptoms of pulmonary edema result. These include cough with production of large amounts of liquid phlegm. Finally, a liquid escapes from the mouth and nose which becomes increasingly frothy and pink- colored.

The length of the clinically silent latency period is inversely proportional to the inhaled dose [73]: after high doses symptoms and discomfort can occur after 2 – 3 h, but after smaller doses these occur after 12 – 20 h. Early indications of a gradually developing pulmonary edema can be provided by a radiography of the lungs, even in the clinically silent latent phase [73]. Initial transient irritation phenomena, such as burning eyes, burning throat, and dry cough, occur only for a short while after inhalation of quite high concentrations (> 3 ppm).

Direct contact with liquid phosgene is said to lead to severe irritation or burning of the skin and mucous membranes [74], [75].

For humans the following concentration- or (dose-) effect relations apply [76]:

TLV, MAK value	0.1 ppm
Odor detection	ca. 0.4 ppm
Odor identification	ca. 1.5 ppm
Irritation in eyes, nose, throat, and bronchial tubes	> 3.0 ppm
Beginning of lung impairment (for concentrations > 0.15 ppm)	ca. 30 ppm · min
Clinical pulmonary edema	> 150 ppm · min
Lethal dose (concentration × time, Lct)	
Lct minimum	ca. 300 ppm · min
Lct_{50}	ca. 500 ppm · min
Lct_{100}	ca. 1300 ppm · min

The characteristic phosgene odor is said to be reminiscent of freshly mown grass or fresh hay. With increasing phosgene concentration, however, a pungent odor dominates. Since odor detection or odor identification is only possible at phosgene concentrations above the TLV or MAK value, the phosgene odor does not provide sufficient warning. Life-threatening poisoning is possible without detection of the odor.

The insidious feature of phosgene poisoning is the substantial freedom from major initial discomfort; there is at first no clinical clue to the dose inhaled. Therefore, a so-called "phosgene indicator badge" was developed at the end of the 1970s [77]. This is a simple, visually readable, passive sampler based on a phosgene indicator paper that is impregnated with a solution of 4-*p*-nitrobenzylpyridine and *N*-benzylaniline. These phosgene indicator badges are now worn routinely in many plants by all employees. When the indicator paper becomes visibly colored, the persons affected should immediately consult a doctor. No specific antidote to phosgene is yet known. Hexamethylenetetramine has only a prophylactic effect, i.e., an effect if administered before phosgene inhalation [71]. Phosgene poisoning can be treated using corticosteroids and positive pressure respiration [71].

In the course of a case of phosgene poisoning, the pulmonary edema usually reaches its climax about 24 h after inhalation. The lethality depends on the dose inhaled. Fairly extensive statistics for fairly long periods of time usually give a lethality of 1 – 4 %. In general the pulmonary edema largely recedes within 3 – 5 d. Care must be taken to avoid pneumonia superinfection.

After surviving phosgene poisoning with pulmonary edema, the affected persons often complain for weeks (sometimes for months) of physical weakness, sweating, and an accelerated

heart beat (tachycardia) accompanying physical exertion. This is apparently a transient circulatory regulation disorder. Permanent reduction of the lung function or ensuing chronic bronchitis is extremely rare [78].

Repeated slight (subclinical) inhalation of phosgene can lead to an increased tolerance for a period of several days. This is explained by the edematous-inflammatory reaction of the blood – air barrier after the first exposure [79]. Thus the thickening of the blood – air barrier works like a protective dam in front of the capillaries; the diffusion path for phosgene becomes greater for later inhalations; more phosgene reacts with organic cell compounds or hydrolyses in the interstice and only a part of the inhaled phosgene is able to reach the capillary wall and exert its harmful effect there.

A chronic phosgene exposure with concentrations below the TLV (MAK) value of 0.1 ppm (8 h/d) is tolerated by healthy persons without harm [80]. The chronic inhalation of higher concentrations, on the other hand, can lead to pulmonary emphysema, without acute poisoning phenomena necessarily appearing in the meantime [81].

Mutagenicity studies with the *S.typhimurium* test system gave negative results [82].

1. History [1]

Farmers have always been anxious to improve crop yields. Some thousand years ago, Chinese farmers used calcined bones and the Incas in Peru used phosphoguano to increase crop output. In Europe, bones have been applied for centuries to French vineyards.

Several seventeenth century publications in Europe mention the beneficial effect of bones as a fertilizer for plant growth.

The German alchemist HENNING BRANDT discovered phosphorus in 1669 by isolating it from urine. In 1769 the Swedish scientist J. G. GAHN discovered that calcium phosphate is the main component of bones. About 30 years later, the conclusion was reached that the fertilizing effect of bones is due mainly to calcium phosphate and not to organic material. In 1797 the British physician GEORGE PEARSON gave the name superphosphate to the phosphate compound (calcium dihydrogenphosphate) found in bone; this name was later applied to fertilizers. Field trials demonstrated that bones should be crushed and applied in very small pieces.

Merchants then moved into the fertilizer business and established local powder mills for bone grinding. Attempts were made to improve fertilizer efficiency by composting bones in earth, animal waste, or plant waste; by boiling bones in water; or by treating them with steam under pressure.

Increased understanding of the fertilizer effect of phosphorus and a rapid increase in the use of bones in the early nineteenth century led to the idea of using chemical treatment of bones to improve fertilizer efficiency. Developments occurred in many countries. HEINRICH W. KÖHLER of Bohemia was probably the first to suggest and file a patent for using acids (especially sulfuric acid) in the processing and commercial production of phosphate fertilizers (1831).

In 1840 JUSTUS VON LIEBIG's theory on phosphorus uptake in plants contributed greatly to acceptance of the product and to rapid worldwide growth of the phosphate fertilizer industry. In the early 1840s the lack of bones as a raw material led to the export of phosphoguano from Peru. The discovery of low-grade mineral phosphates in France and England eased the raw material situation, but the development of the phosphate industry was secured by the discovery of large sedimentary phosphate deposits in South Carolina. The deposits were rediscovered as phosphate rock in 1859; mining began in 1867, and in 1889 the mine supplied 90 % of the worldwide phosphate fertilizer production.

The production of ammonium phosphate fertilizers by ammoniation of phosphoric acid began around 1917 in the United States. The Haber – Bosch process boosted this product line, and in 1926 the IG Farbenindustrie in Germany announced the development of a series of multinutrient (compound) fertilizers based on crystalline ammonium phosphate.

Separation of calcium sulfate from the superphosphate slurry by increasing the sulfuric acid/rock ratio and use of phosphoric acid for acidulation led to the development of concentrated (triple) superphosphates and commercialization in ca. 1890.

The treatment of phosphate rock with nitric acid (nitrophosphate process) was developed in the late 1920s by the Norwegian ERLING B. JOHNSON. The IG Farbenindustrie, DSM in The Netherlands, and Norsk Hydro in Norway commercialized this route for complex fertilizer production in the 1930s.

In Europe, calcium silicophosphate fertilizer is produced as a byproduct of the steel industry. Iron ore may contain phosphorus, which can be removed by slagging out with lime. The product is sold under the name Thomas phosphate or basic slag. Many attempts have been made

to produce similar fertilizer products by thermal treatment of phosphate rock with additives but most were unsuccessful due to high energy costs. Small amounts of fused magnesium phosphate and calcined defluorinated phosphate are produced in Brazil, China, Korea, and Japan [2].

2. Terminology

Phosphorus Content. The phosphorus-containing component of phosphate rock is apatite. *Fluorapatite* [*1306-05-4*] is the most common phosphate rock mineral. The correct formula of fluorapatite is $Ca_{10}F_2(PO_4)_6$, but it can be simplified to $Ca_5F(PO_4)_3$.

In commercial trading of phosphate rock, the phosphorus content is calculated as the weight percentage of tricalcium phosphate, $Ca_3(PO_4)_2$, and expressed as the bone phosphate of lime (BPL) or the total phosphate of lime (TPL). Tricalcium phosphate is not present as such in phosphate rock, but to simplify the relationship between BPL and fluorapatite, the formula of fluorapatite is sometimes expressed as $3\,Ca_3(PO_4)_2 \cdot CaF_2$.

The phosphorus in fertilizers is supplied as orthophosphate (referred to here as phosphate), PO_4^{3-}, but the content is generally expressed as the weight percentage of phosphorus pentoxide (P_2O_5) or, incorrectly, as phosphoric acid. Similarly, the contents of potassium, magnesium, and calcium are given as the weight percentage of their oxides: potassium oxide (K_2O), magnesium oxide (MgO), and calcium oxide (CaO). In the Scandinavian countries (except Iceland) and Ireland, however, the nutrient contents are expressed as elements (P, K, Mg, Ca).

$$\begin{aligned}
BPL &= 2.185 \times P_2O_5 = 5.008 \times P \\
P_2O_5 &= 0.458 \times BPL = 2.291 \times P = 0.724 \times H_3PO_4 \\
P &= 0.200 \times BPL = 0.436 \times P_2O_5 \\
&= 0.316 \times H_3PO_4
\end{aligned}$$

PO_4^{3-} = (ortho)phosphate ion
HPO_4^{2-} = hydrogen(ortho)phosphate ion
$H_2PO_4^{-}$ = dihydrogen(ortho)phosphate ion
H_3PO_4 = phosphoric acid

Types of Fertilizer. The production routes for phosphate fertilizers are summarized in Figure 1.

Superphosphate fertilizers (Chap. 8) are produced by treating phosphate rock with acid to give calcium dihydrogenphosphate.

The product obtained with sulfuric acid is called *single* (*or normal*) *superphosphate* (SSP). It is produced as superphosphate powder (run-of-pile), which later can be granulated to form 2 – 5 mm particles. Single superphosphate contains mainly calcium dihydrogenphosphate and calcium sulfate.

The most common product is, obtained by treatment of phosphate rock with phosphoric acid, is called *triple superphosphate* (TSP) (or concentrated superphosphate in North America). Triple superphosphate is produced either by use of run-of-pile powder as an intermediate or by a direct slurry granulation process.

Of minor importance is *double superphosphate*, which is a mixture of single and triple superphosphates. The term double superphosphate may cause some confusion because it was used earlier as a name for triple superphosphate.

Partly acidulated phosphate rock (PAPR, see Section 12.2) is produced in the same way as superphosphates, but with less sulfuric acid, to obtain ca. 50 % water-soluble P_2O_5. Annual production is negligible compared to other superphosphates.

Ammonium phosphate fertilizers (Chap. 9) contain ammonium dihydrogenphosphate [*7722-76-1*], $NH_4H_2PO_4$ (referred to in the fertilizer trade as monoammonium phosphate, MAP), and diammonium hydrogenphosphate [*7783-28-0*], $(NH_4)_2HPO_4$ (referred to as diammonium phosphate, DAP).

Compound (multinutrient) NP or NPK fertilizers are made by acidulating rock with sulfuric acid (Chap. 10) or nitric acid (Chap. 11).

Ground phosphate rock (Section 12.1) may also be used directly as a fertilizer. Basic slag (Section 12.2) is a fertilizer byproduct of the steel industry.

3. Composition of Phosphate Fertilizers

The major chemical components of the most common phosphate fertilizers are given in Table 1.

In phosphate rock, the F^- in fluorapatite may be replaced by OH^- and Cl^-; PO_4^{3-} by

Figure 1. Primary production routes for phosphate fertilizers

CO_3^{2-}, SO_4^{2-}, CrO_4^{2-}, and SiO_4^{4-}; and Ca^{2+} by Na^+, K^+, Mg^{2+} and heavy metals. Possible metal compounds in phosphate fertilizers have been reported [3][4][5][6][7]. Their formation depends on process conditions and concentrations.

Dissolved iron and aluminum in superphosphate precipitate slowly as complex salts. High concentrations of aluminum and iron form amorphous aluminum and iron phosphate in superphosphates, which revert to crystalline calcium metal phosphate during production and storage. The most common components are $CaFe_2(HPO_4)_4 \cdot nH_2O$ and $CaAl_2(HPO_4) \cdot nH_2O$; $(Fe,Al)CaH(PO_4)_2 \cdot nH_2O$ may also be present. The same calcium metal phosphates are formed when phosphoric acid containing free calcium ions is ammoniated.

When phosphoric acid is ammoniated, the metals always seem to be present as metal ammonium phosphates in crystalline form, amorphous form, or as pyrophosphate gel.

Crystalline form:
$FeNH_4(HPO_4)_2$
$AlNH_4(HPO_4)_2$
Amorphous form:
$FeNH_4(HPO_4)_2 \cdot nH_2O$
$AlNH_4(HPO_4)_2 \cdot nH_2O$
$Mg(NH_4)_2(HPO_4)_2 \cdot nH_2O$
$AlNH_4F_2(HPO_4) \cdot nH_2O$
$FeNH_4F_2(HPO_4) \cdot nH_2O$
Pyrophosphate gel:
$(Mg, Al, Fe)NH_4FHP_2O_7 \cdot nH_2O$

Phosphate solubilities are measured in different ways to indicate plant availability (→ Fertilizers, Chap. 6.3.):

1) Extraction with water
2) Extraction with citrate solution (neutral ammonium citrate solution)
3) Extraction with 2 % citric acid
4) Extraction with 2 % formic acid
5) Determination of total phosphate content

Calcium dihydrogenphosphate $Ca(H_2PO_4)_2$ (monocalcium phosphate, MCP), MAP, and DAP are water soluble; calcium hydro-

[a] Range for P_2O_5 given without K addition. [b] Compound NP and NPK fertilizers based on the sulfuric acid route; the P component may be based on MAP, DAP, SSP, TSP, or a mixture; [c] Compound NP and NPK fertilizers based on the nitrophosphate route; specific values given for 75% water solubility P_2O_5. [d] Partially acidulated phosphate rock. [e] Estimated average P_2O_5 content in given type of fertilizer. [f] P:P (total) denotes the ratio of the phosphorus content in the specified chemical component to the total phosphorus content of the fertilizer.

genphosphate, $CaHPO_4$ (dicalcium phosphate, DCP), is citrate soluble (not water soluble).

Calcium metal phosphates as crystalline precipitates are citrate soluble.

Metal ammonium phosphates as amorphous precipitates or pyrophosphate gel are citrate soluble. Metal ammonium phosphates as crystalline precipitates are not usually citrate soluble.

Superphosphates normally contain >90 % water-soluble and >98 % citrate-soluble P_2O_5. Ammonium phosphates contain >85 % watersoluble and >99 % citrate-soluble P_2O_5. Compound NPK fertilizers contain >70 – 75 % water-soluble and >99 % citrate-soluble P_2O_5.

In partly acidulated rock fertilizers, the P_2O_5 solubility in water and citrate is ca. 45 – 50 % and the solubility in citrate solution somewhat higher.

Ground phosphate rock has no citrate-soluble P_2O_5 but solubility in 2 % citric acid may be 5 – 53 % and solubility in 2 % formic acid may be as high as 86 %. Basic slag (calcium silicophosphate) has no water-soluble P_2O_5, but citrate solubility is reported to be up to 90 % and the citric acid solubility up to 97 % [8].

4. Phosphate Rock

Phosphate rock is virtually the sole raw material for phosphate fertilizers. The primary source is sedimentary phosphate rock (phosphate precipitated from seawater and bones) but magmatic (igneous) phosphate rocks are also important.

Phosphate rock contains calcium phosphates as apatites, mainly fluorapatites. It is mined in almost 30 countries, and phosphate fertilizers are produced in 26 countries in Europe, 13 in America, 9 in Africa, 13 in Asia, and 2 on the Australian continent [9].

About 90 % of mined phosphorus is used in fertilizers, being divided almost equally among superphosphates, ammonium phos-

phates, and compound fertilizers (including nitrophosphates).

5. Economic Aspects

5.1. Phosphate Rock

Phosphate rock reserves of varying composition and quality are widely distributed. Exploitation of deposits occurs in many countries, but large-volume production for captive use and export is limited to a few countries. Total world rock production in 1989 was 161.4×10^6 t and was divided as follows (10^6 t):

United States	49.9
Former Soviet Union	35.0
People's Republic of China	18.5 *
Morocco	18.0
Jordan	6.7
Tunisia	6.6
Israel	3.9
Brazil	3.7
Togo	3.4
Republic of South Africa	3.0
Senegal	2.3
Syria	2.3

* Down from 24.8×10^6 t in 1988 due to market disruption

The four major producers of rock account for 75 % of world output. The output of former Soviet and Chinese phosphate rock mines was essentially used for domestic consumption.

Since the early 1970s, phosphate rock has become a less important export product in comparison with processed phosphate products (mainly phosphoric acid, ammonium phosphates, and triple superphosphate). World export of phosphate rock was 43.5×10^6 t in 1989 (down from a peak of 53.4×10^6 t in 1979) and was divided as follows (10^6 t):

Morocco	12.4
United States	8.3
Jordan	5.9
Togo	3.3
Former Soviet Union	3.2
Israel	2.4
Syria	1.7
Senegal	1.4
Nauru	1.2
Republic of South Africa	1.1
Tunisia	1.1

The four leading export countries accounted for 69 % of world trade.

The shift away from phosphate rock as the major vehicle for trade in phosphates results from the development of vertically integrated industries at or near mine sites. The key element in these operations is phosphoric acid capacity, which allows a concentrated, gypsum-free product to be transported to market.

The shift toward captive processing of phosphate rock is reflected in a significant change in the pattern of phosphate rock consumption and world trade. The total trade in rock continues to decrease and appears to have fallen below 40×10^6 t/a in 1990 for the first time since 1970. On the other hand, the tonnages delivered to downstream processing industries are now substantial. Total worldwide consumption of phosphate rock in 1989 was 158.9×10^6 t and was divided as follows (10^6 t):

Western Europe	17.0
Eastern Europe	42.2
Former Soviet Union	31.8
North America	42.4
Africa	14.4
Morocco	5.2 *
Republic of South Africa	2.1
Tunisia	5.1
Central America	2.4
Mexico	2.4
Australasia	2.5
Australia	1.7
Middle East	3.9
Iraq	1.1
Israel	1.4
Jordan	1.0
Asia	28.7
People's Republic of China	18.8
India	3.0
Indonesia	1.1
Japan	1.6
South Korea	1.5
South America	4.6
Brazil	4.1

* Down from 10.6×10^6 t in 1988 as a result of market disruption.

A comparison of phosphate rock consumption statistics with production and export statistics reflects the development of downstream processing facilities in many rock-exporting countries. Demand for phosphate rock has thus receded in a number of regions, notably Western Europe and Japan.

Phosphate rock statistics are generally expressed as tonnes of product. The phosphorus content of the rock varies. Rock of sufficiently high phosphorus content (grade) to be acceptable commercially contains 30–40 % P_2O_5 (66–87 BPL).

The majority (ca. 90 %) of phosphate rock produced is converted into fertilizer. Smaller, nonfertilizer end uses account for ca. 10 % of phosphate rock consumption; the most important are the manufacture of detergents and animal feed additives.

5.2. Phosphate Fertilizer Consumption

Worldwide consumption of phosphate fertilizers continues to grow, but during the 1980s growth was erratic and less dynamic than in the 1960s and 1970s. Consumption (in 10^6 t P_2O_5) was as follows (in 10^6 t):

1960	9.7
1965	14.0
1970	19.7
1980	31.6
1985	33.0
1986	34.8
1987	36.4
1988	37.7
1989	36.6

A number of factors will contribute to the future consumption of phosphate fertilizers:

1) The agricultural sector in the export-oriented countries of the developed world has suffered consistently from overproduction and mounting subsidy bills. In addition to poor farm economics, government programs have been aimed at reducing crop production.
2) In many developed countries, years of regular phosphate application have led to a buildup of phosphate soil reserves. As farm economics have deteriorated, farmers have been content to exploit the soil reserves by reducing phosphate application.
3) Environmental concern about the consequences of overfertilization and runoff of nutrients in groundwater has led to a more accurate application of nutrients in many countries.

In Western Europe, phosphate fertilizer consumption peaked in 1979 at 6.8×10^6 t of P_2O_5; pressures on agriculture from the Common Agricultural Policy (CAP), the General Agreement on Tariffs and Trade (GATT) negotiations, and environmental groups indicate that consumption levels are unlikely to recover and may stabilize close to 5×10^6 t of P_2O_5.

In Central Europe and the former Soviet Union, phosphate fertilizer consumption increased steadily during most of the 1980s in line with economic policies. A peak of 11.6×10^6 t of P_2O_5 was recorded in 1988. Changed economic circumstances may lead to reduction.

Consumption of phosphate fertilizer in North America peaked in 1980 at 5.6×10^6 t of P_2O_5. In the latter half of the 1980s, annual use fluctuated between 4.3 and 4.6×10^6 t. Decline in consumption is not anticipated. At 2.4×10^6 t P_2O_5 in 1989, phosphate fertilizer usage in South America was down some 0.4×10^6 t P_2O_5 over 1980. Demand in Brazil has proved the single most important variable, fluctuating by as much as 1×10^6 t/a in the 1980s. In Africa, annual demand fluctuated between 1.3×10^6 t (1981) and 0.9×10^6 t (1989) due to civil conflict, economic crises, and drought.

Asia had consistent growth in phosphate fertilizer consumption during the 1980s. This reflects the constantly increasing demand for food by the rapidly growing population. Chinese consumption almost doubled during the 1980s, reaching 5.3×10^6 t of P_2O_5 in 1989. In the Middle East, P_2O_5 consumption (including Australasia) in 1989 stood at 12.2×10^6 t, 33 % of the world total.

5.3. Phosphate Fertilizer Production

Changes in the phosphate industry toward vertical integration and the trading of processed P_2O_5 products rather than phosphate rock have resulted in significant shifts in phosphate fertilizer product patterns. The importance of low-grade phosphate fertilizers (i.e., products with a low P_2O_5 content) has declined significantly. These include single superphosphate (typically 18–22 % P_2O_5) and basic slag (typically 13–15 % P_2O_5). Not only does the low nutrient content make such products more expensive to transport, handle, and apply, but production economics have made some of them unattractive.

High-nutrient fertilizers now dominate the world phosphate fertilizer market and fall into three categories:

1) Ammonium phosphates
2) Triple (or concentrated) superphosphate
3) Binary and ternary compound (or complex) fertilizers

The ammonium phosphate category comprises two main fertilizer products: diammonium phosphate, DAP ($N-P_2O_5$ content: 18 – 46; i.e., 18 wt % N and 46 wt % P_2O_5) and monoammonium phosphate, MAP ($N-P_2O_5$ content: 11 – 53).

Triple (or concentrated) superphosphate is a straight, single-nutrient phosphate product (typical P_2O_5 content 48 wt %).

Compound (multinutrient) fertilizers are produced in various combinations (→ Fertilizers, Chap. 3.1.). The NPK fertilizers contain all three main fertilizer nutrients, i.e., nitrogen, phosphorus, and potassium (typical N-P_2O_5-K_2O content in weight percent: 16-16-16, NP fertilizers contain no potash (nutrient content typically 22-20-0), PK fertilizers are produced mainly in Western Europe (nutrient content typically 0-25-25).

In 1989, world phosphate fertilizer production amounted to 38.6×10^6 t of P_2O_5. Production breakdown follows (in 10^6 t):

Single superphosphate	7.0
Triple superphosphate	4.6
Ammonium phosphates	13.7
Compound fertilizers	10.3
Other low-analysis phosphates	3.0

Single superphosphate retains its importance in some developing countries and in Eastern Europe. In 1989 the People's Republic of China accounted for 2.5×10^6 t of P_2O_5 production, Eastern Europe for almost 2×10^6 t, and India for 0.5×10^6 t. As economic conditions in Central Europe change, single superphosphate will probably be displaced by more concentrated products.

Production of *triple superphosphate* (known as concentrated superphosphate in North America) is widely dispersed. More than 1×10^6 t of P_2O_5 was produced in Eastern Europe in 1989, but this is likely to decrease. Producers in the United States accounted for ca. 0.8×10^6 t of P_2O_5, and North African and Middle Eastern industries for an additional 1.1×10^6 t. Not all triple superphosphate is applied directly to soil. It is often blended at the distributor or even the farm level with other nutrients and applied as compound fertilizer. The same is true of single superphosphate, although to a lesser degree.

Triple superphosphate is the least important export product. In 1989, world trade amounted to 1.5×10^6 t of P_2O_5 (3.3×10^6 t of product). Approximately 0.9×10^6 t of these exports originated in North Africa and the Middle East, and 0.25×10^6 t in the United States.

Ammonium phosphates were developed in the United States primarily as components of blended fertilizers (bulk blends): DAP is the most important product, world production amounting to 9.3×10^6 t of P_2O_5 in 1989, 5.8×10^6 t of this being produced in North America. In 1989, U.S. exporters shipped ca. 3.6×10^6 t. Morocco is now the second most important exporter (0.5×10^6 t P_2O_5), and output is growing. The production of MAP is concentrated primarily in the former Soviet Union and North America. In 1989, world output was 4.4×10^6 t of P_2O_5, of which 2.5×10^6 t was manufactured in the former Soviet Union and 1.3×10^6 t in North America. These products have become so attractive in terms of cost effectiveness on the world market that an increasing proportion of ammonium phosphate is being used as a direct application fertilizer, particularly in less-developed countries.

Compound fertilizers are a development of the European fertilizer industry. They may be produced by treating phosphate rock with sulfuric acid (the sulfur, wet process phosphoric acid, or ammonium phosphate route) or with nitric acid (the nitrophosphate route). In addition, fertilizer components such as ammonium phosphate may be mixed physically to produce blended compound fertilizers. Blending often occurs at the wholesale or retail level; the total volume of blended compounds is therefore not reflected in consumption (delivery) statistics.

In 1989, the chemical production of compound fertilizers exceeded 2×10^6 t of P_2O_5 in both Eastern and Western Europe and 1×10^6 t in North America. However, considerable pressure has been exerted on European industries from imported DAP and triple superphosphate (which will lead to continuing rationalization of this sector).

Although a significant amount of regional trade in P_2O_5 fertilizers such as NPKs occurs within Western Europe, between the former Soviet Union and Central Europe, interregional trade in phosphate fertilizers is now dominated by vertically integrated producers. The United States dominates the international market for DAP (see above).

6. Phosphorus Uptake by Plants

[10–12]

Role in Plant Nutrition. Phosphorus is essential for vital growth processes in plants because it is a constituent of nucleic acids. It is also a constituent of phospholipids. Phosphorus compounds (coenzymes) are involved in respiration, energy transfer, and the efficient utilization of nitrogen. See also → Fertilizers, Chap. 2.1.2.

Phosphorus is of special importance in root development and in the ripening of seeds and fruit. The application of phosphate fertilizer to soils that are low or deficient in available phosphate improves root development and seedling growth, giving the crops a better start.

Phosphorus is taken up by plants as the dihydrogenphosphate ($H_2PO_4^-$) or the hydrogenphosphate (HPO_4^{2-}) ion.

Phosphorus Deficiency Symptoms. In phosphorus deficiency the growth of plant tops and roots is greatly restricted: shoots are short and thin, growth is upright and spindly; leaves are small, and defoliation is premature; lateral shoots are few in number, and lateral buds may die or remain dormant; blossoming is greatly reduced, resulting in poor yields of grain and fruit. These symptoms also apply to nitrogen deficiency, but with phosphate deficiency the leaf color is generally a dull, bluish green, usually with a purple tint (rather than yellow or red). Leaf margins may also show brown scorching.

Forms of Phosphate in the Soil. Most phosphate in the soil is present in the solid phase; only a small amount is dissolved in the soil solution. Solid-phase phosphate occurs partly in organic form (30 – 50 %), but in mineral soil it exists mainly in inorganic form (50 – 70 %). The three major components of *organic soil phosphate* are nucleic acids, phospholipids, and phytin with its derivatives. Organic phosphate is continuously released as HPO_4^{2-} ions by microbial degradation of organic soil matter. However, this phosphate release does not always coincide with maximum plant uptake.

Most *inorganic soil phosphates* fall into two groups: those containing calcium, and those containing iron and aluminum. The calcium compounds of greatest importance are apatites with the general formula $Ca_5(F, Cl, OH, 1/2\,CO_3)(PO_4)_3$; calcium hydrogenphosphate, $CaHPO_4$ (dicalciumphosphate, DCP); and calcium dihydrogenphosphate, $Ca(H_2PO_4)_2$ (monocalciumphosphate, MCP).

Fluorapatite is the most insoluble of these compounds and is therefore unavailable to plants. In contrast, MCP and DCP are readily available for plant growth. Except in recently fertilized soil, these two compounds are present in very small quantities because they readily react to form more insoluble compounds.

Figure 2. Main soil phosphate fractions

The iron and aluminum phosphates in soil are probably hydroxyphosphates. They are very stable in acid soil and are extremely insoluble.

Three inorganic soil phosphate fractions are important in terms of plant nutrition (Fig. 2):

1) Phosphate in soil solution: dissolved phosphates available for plant uptake

2) Phosphate in the labile pool: often absorbed on mineral soil particles and can rapidly go into soil solution
3) Phosphate in the nonlabile fraction: only very slowly released into the labile pool

Phosphate dissolved in soil solution can be taken up by plants. Phosphate removed from this pool is replenished by phosphate from the labile pool. Nonlabile (insoluble) phosphate is released very slowly into the labile pool–too slowly to make a significant contribution to the crop in one growing season.

Effect of Soil on Phosphate Availability. The pH determines the phosphate form in soil solution. In very acid solution, only $H_2PO_4^-$ ions are present. As pH increases the HPO_4^{2-} ions and then the PO_4^{3-} ions dominate. At pH 7.0 the proportions of $H_2PO_4^-$ and HPO_4^{2-} ions are roughly equal:

$$\underset{\text{Acid solution}}{H_2PO_4^-} \underset{}{\overset{H^+}{\rightleftharpoons}} HPO_4^{2-} \underset{}{\overset{H^+}{\rightleftharpoons}} \underset{\text{Very alkaline solution}}{PO_4^{3-}}$$

Although the $H_2PO_4^-$ ion is generally considered to be more available than the HPO_4^{2-} ion, both can be taken up by plants. However, in soil this relationship is complicated by other compounds and ions.

In acid soil, soluble iron, aluminum, and manganese react with $H_2PO_4^-$ ions to form insoluble phosphates that are unavailable for plant growth:

$$\underset{\text{Soluble}}{Al^{3+} + H_2PO_4^-} + 2\,H_2O \longrightarrow 2\,H^+ + \underset{\text{Insoluble}}{Al(OH)_2H_2PO_4}$$

In most acid soils the concentration of iron and aluminum ions exceeds that of $H_2PO_4^-$ ions, and only minute quantities of phosphate remain immediately available to plants. Phosphate can also be fixed by hydrous oxides, kaolinite, montmorillonite, and illite. Alkaline soil containing an excess of exchangeable calcium (e.g., calcium carbonate) also precipitates phosphates:

$$\underset{\text{Soluble}}{Ca(H_2PO_4)_2} + 2\,CaCO_3 \longrightarrow \underset{\text{Insoluble}}{Ca_3(PO_4)_2} + 2\,CO_2 + 2\,H_2O$$

Because insoluble phosphates are formed in both acid and alkaline soils, maximum phosphate availability is obtained at a soil pH of 6.0–7.0. Even in this range, phosphate availability may be low, and added soluble phosphates can be readily converted into unavailable forms.

Use of Phosphate as a Fertilizer. Phosphate ions are relatively immobile in soil compared to nitrate, and are taken up by plants from the soil solution at the root surface. The critical time for phosphate supply to the plant is in the seedling stage, when seed reserves of phosphate have been exhausted and the root system has not developed sufficiently to supply phosphate needs.

Two strategies are employed with phosphate fertilizers:

1) Sufficiently high phosphate levels are built up in soil to meet the crop requirement for phosphate ions. Crops with shallow root systems (e.g., potatoes) require a higher concentration of phosphate in soil solution to sustain growth than crops with extensive root systems (e.g., cereal).
2) A small reservoir of phosphate ions is provided near the site at which seedling roots develop (a hot spot of phosphate-enriched soil). Enriched hot spots can be created only if the phosphate fertilizer dissolves rapidly in the soil. For most soil the fertilizer must be water- or citrate-soluble.

In some situations the association of roots with microorganisms (endotropic mycorrhizae) increases phosphate uptake by a number of crops. However, at present this seems to be of only agronomic importance in soil with a very low phosphate content. Similarly, root exudates can influence chemical and microbial activity in the root zone and can increase phosphate uptake where soil phosphate supply is marginal.

High-yield crops used in modern agriculture demand high levels of soluble phosphate in the soil. This can be achieved only by adding materials (fertilizers) containing soluble phosphates. The natural soil phosphate level is usually not sufficient.

The quantity of soluble phosphate fertilizer added for a particular crop depends on the phosphate removed in the harvested yield, the response of the crop to the fertilizer, and the available phosphate level of the soil in which the crop is grown. The amounts of phosphate removed by

crops are as follows (kilogram of P_2O_5 per tonne of fresh material) [13]:

Sugar beets, swede roots, cabbage, carrots, onions	0.7 – 0.9
Potato, kale, maize, French beans, beetroot, cauliflower, silage grass, cereal straw, vining peas, broad beans	1.0 – 1.6
Brussel sprouts	2.1 – 2.6
Grass, hay, cereal grain, dried peas	5.9 – 8.8
Field beans	11
Oilseed rapeseed	16

7. Chemical Equilibria in Fertilizer Production

In acidic soil, fluorapatite in porous phosphate rocks may slowly be broken down to form water-soluble phosphate ions. In fertilization, a strong acid is used to break down the apatite to hydrogenphosphates.

The system of phosphate fertilizers can be understood by means of acid – base and solid –liquid chemical equilibria. The primary acid –base equilibria involve phosphoric acid, sulfuric acid, nitric acid, and ammonia. The main solid – liquid equilibria involve ammonium phosphates, calcium phosphates, and water.

Fertilizer Acids. Most important is the phosphoric acid equilibrium [14]:

$$H_3PO_4 \rightleftharpoons H^+ + H_2PO_4^- \quad K = 10^{-2.13}$$

$$H_2PO_4^- \rightleftharpoons H^+ + HPO_4^{2-} \quad K = 10^{-7.2}$$

$$HPO_4^{2-} \rightleftharpoons H^+ + PO_4^{3-} \quad K = 10^{-12.4}$$

These equilibria can be represented in different ways: as a function of mole percent and pH (→Phosphoric Acid and Phosphates, [15] or as a function of logarithmic concentration and pH (also called a Bjerrum diagram, Fig. 3) [16–21].

Figure 3. Phosphoric acid equilibria in solution [17]

Sulfuric acid and nitric acid are also important acids in phosphate fertilizer production. The equilibrium reactions are [14]

$$H_2SO_4 \rightleftharpoons H^+ + HSO_4^- \quad K = >1$$

$$HSO_4^- \rightleftharpoons H^+ + SO_4^{2-} \quad K = 10^{-1.99}$$

$$HNO_3 \rightleftharpoons H^+ + NO_3^- \quad K = 10^{1.37}$$

These equilibria can also be illustrated in a logarithmic diagram.

Ammonium Phosphates. Ammoniation of phosphoric acid involves the following reactions [14]:

$$NH_4^+ \rightleftharpoons H^+ + NH_3 \quad K = 10^{-9.24}$$

$$NH_4^+ + H_2PO_4^- \rightleftharpoons NH_4H_2PO_4 \text{ (MAP)}$$

$$2\,NH_4^+ + HPO_4^{2-} \rightleftharpoons (NH_4)_2HPO_4 \text{ (DAP)}$$

These equilibria can be represented in a logarithmic diagram by combination of the ammonia and phosphoric acid constants (Fig. 4).

Figure 4. Ammonium phosphate equilibria in solution

Figure 5. Effect of NH_3/H_3PO_4 molar ratio on the solubility of ammonium phosphates at 75 °C [23]

The maximum concentrations of NH_4^+ and $H_2PO_4^-$ ions necessary for MAP production are present in the pH range 2.5 – 7.0 (parallel lines at the top of Fig. 4). The optimum point for MAP production lies where the concentrations of H_3PO_4, (phosphoric acid) and HPO_4^{2-} (the DAP component) are minimized. This is the point where the concentrations of H_3PO_4 and HPO_4^{2-} equal each other, their concentrations lines cross at pH 4.65. A 1 % aqueous solution of MAP has a pH of 4.5 [22].

The maximum concentrations of NH_4^+ and HPO_4^{2-} ions necessary for DAP production are present at about pH 8.0 (parallel lines at the top of Fig. 4). The optimum point for DAP production lies where the concentrations of $H_2PO_4^-$ (the MAP component) and NH_3 (ammonia) are minimized. This is the point where the concentrations of $H_2PO_4^-$ and NH_3 equal each other, their concentrations lines cross at pH 8.1. A 1 % aqueous solution of DAP has a pH of 8.0 [22].

The concentration curves of HPO_4^{2-} and $H_2PO_4^-$ in Figure 4 give the fractions of DAP and MAP present as a function of pH in the neutralization process.

In fertilizer production, high pH must be avoided to minimize formation of free ammonia in the liquid, which is a potential source of loss.

Crystallization. Neutralization and evaporation are used in most fertilizer-producing processes. Knowledge of solubility and crystallization in the system is important. In neutralizing phosphoric acid, the water solubility of a mixture of H_3PO_4, MAP, and DAP is usually presented as shown in Figure 5.

In Figure 6 the N/P molar ratio is plotted as a function of MAP – DAP content.

Figure 6. N/P molar ratio as a function of MAP – DAP content

If only water, MAP, and DAP are considered, point 1 in Figure 5 shows that at 75 °C, a saturated solution consists of 75 wt % MAP – DAP, and 25 wt % water. The N/P molar ratio is 1.45, corresponding to 52 wt % MAP and 48 wt % DAP (Fig. 6). The composition at point 1 is therefore 25 wt % water, 39 wt % MAP, and 36 wt % DAP. For this composition a reduction in temperature below 75 °C results in crystallization.

A more informative way of presenting the water – MAP – DAP system is to use a phase diagram (Fig. 7). Points 1 in Figures 5 and 7 represent the same composition. The temperature curves in Figure 7 give the crystallization temperature for a given concentration of MAP, DAP, and water. Point 1 is on the borderline between the crystallization areas for MAP and DAP; MAP and DAP will both crystallize as the temperature is reduced below 75 °C.

Figure 7. Phase diagram of MAP – DAP – water [24]

A solution given by point 2 in Figure 7 (73 % MAP, 22 % DAP, 5 % water) starts to crystallize at 170 °C. If the temperature is reduced, MAP begins to crystallize. As MAP crystallizes, the liquid composition changes along a straight line through point 2, with its origin at the MAP corner toward point 3. When the liquid phase composition reaches point 3, both MAP and DAP crystallize. Further cooling results in the crystallization of MAP and DAP. The liquid phase composition moves along the borderline between the MAP and DAP crystallization areas. At point 4 the

last liquid phase crystallizes at the eutetic temperature well below −20 °C (to give ice, MAP, and DAP).

Figure 8. Phase diagram of AN – MAP – water [25]

Figure 9. Phase diagram of AN – MAP – DAP [26]

Compound Fertilizers. In compound fertilizers the nitrogen content is usually increased by the addition of ammonium nitrate (AN). A system without DAP can be represented by the AN – MAP – water phase diagram shown in Figure 8. The MAP area is dominant. Compositions with a high MAP content and a low water content tend to supercool (undercool).

If the liquid phase of the compound fertilizer melt also contains DAP, a quaternary tetrahedral phase diagram must be used. Figures 7 and 8 represent two sides of the tetrahedron. Figure 9 gives the AN – MAP – DAP diagram representing the "base" of the tetrahedron. An anhydrous melt is difficult to obtain in compositions with a high DAP content.

For a melt with the composition given by point 1, MAP starts to crystallize if the temperature is reduced below 180 °C (Fig. 9). Only MAP crystallizes until the temperature reaches 140 °C (point 2); then both MAP and DAP begin to crystallize. On further cooling the composition of the liquid phase follows the borderline between the MAP and DAP crystallization areas. The last liquid crystallizes at the eutectic temperature of ca. 130 °C (point 3).

With increasing water content, the system becomes a quaternary system. To simplify the tetrahedral phase diagram, the water level is kept constant while the three other components are varied. This corresponds to cutting the tetrahedron at a given water content. Figure 10 shows a section through such a tetrahedron, where the water content for all compositions is 10 wt %.

Figure 10. Phase diagram of AN – MAP – DAP with 10 % water [27]

Three primary crystallization areas exist. The lines represent compositions at which the liquid phase is in equilibrium with two solid phases. For one composition the liquid phase is in

equilibrium with the three solid phases, AN(s), MAP(s), and DAP(s).

Calcium Phosphates. The phosphate component in superphosphates, MCP, is produced as follows:

$$Ca_5F(PO_4)_3 + 7\,H_3PO_4 \rightleftharpoons 5\,Ca(H_2PO_4)_2 + HF$$

Phosphoric acid is produced by the sulfuric acid treatment of phosphate rock, gypsum ($CaSO_4$) is formed as a byproduct. In triple superphosphate production, gypsum is separated from phosphoric acid prior to MCP formation. If calcium sulfate ends up in the product, it can be considered to be an inert solid.

In nitrophosphate processing, ca. 50 % of the remaining calcium in the phosphoric acid mother liquor reacts to give DCP, $CaHPO_4$, during neutralization.

Both superphosphate and nitrophosphate processing involve calcium phosphate solid – liquid equilibria:

$$Ca^{2+} + 2\,H_2PO_4^- \rightleftharpoons Ca(H_2PO_4)_2\,(s)\ \text{MCP}$$

$$Ca^{2+} + HPO_4^{2-} \rightleftharpoons CaHPO_4(s)\ \text{DCP}$$

Because these equilibria depend on ion concentration and temperature, the phase diagram described by GMELIN may be used to determine which calcium phosphate precipitates (Fig. 11) [28].

Figure 11. Phase diagram for calcium phosphates [28] The lines indicate the minium CaO content in the liquid necessary for calcium phosphate precipitation

MCP is produced under the conditions used in superphosphate production (high liquid P_2O_5 concentration); DCP is produced under the conditions used in nitrophosphate processing (high temperature, lower liquid P_2O_5 concentration).

When the compound-fertilizer route is based on superphosphates, MCP is partially converted to DCP and MAP during neutralization with ammonia:

$$Ca(H_2PO_4)_2 + NH_3 \longrightarrow CaHPO_4 + NH_4H_2PO_4$$

In compound-fertilizer granulation, both MCP and DCP are in the solid state and can be considered as inert.

Additives in Compound-Fertilizer Production. Potassium salts may be added in compound-fertilizer production:

$$KCl + NH_4NO_3 \rightleftharpoons KNO_3 + NH_4Cl$$

$$K_2SO_4 + 2\,NH_4NO_3 \rightleftharpoons 2\,KNO_3 + (NH_4)_2SO_4$$

To achieve steady state, the potassium salt has to be dissolved in a multicomponent melt. This may affect salt crystallization and melt viscosity (Fig. 12). If this reaction is not controlled, the liquid phase may increase during granulation or storage.

Figure 12. Crystallization points for potassium chloride dissolved in an 86 % AN – 14 % MAP melt with 0.5 % water [29]

Other salts added to MAP- and DAP-containing melts (e.g., ammonium sulfate, magnesium sulfate, dolomite, borax, micronutrients) can be considered as inert salts in phosphate fertilizer production.

8. Superphosphates

For definitions, see Chapter 2.

8.1. Single Superphosphate

8.1.1. Chemistry

Single superphosphate is produced by acidulation of finely ground phosphate rock with sulfuric acid. Many chemical reactions occur when the phosphate mineral is mixed with sulfuric acid (70 %). The mixture is liquid for 2 – 10 min but solidifies in the next 5 – 10 min.

After 40 – 60 min the superphosphate product is transported to storage where reaction is completed after 3 – 10 days. The reaction rates depend on the type and particle size of the ground phosphate rock, the type and concentration of trace elements in the rock, and the concentration and amount of sulfuric acid.

The primary overall reaction for fluorapatite is

$$2\,Ca_5F(PO_4)_3 + 7\,H_2SO_4 \longrightarrow 3\,Ca(H_2PO_4)_2 + 7\,CaSO_4 + 2\,HF$$

It has two consecutive stages:

$$Ca_5F(PO_4)_3 + 5\,H_2SO_4 \longrightarrow 3\,H_3PO_4 + 5\,CaSO_4 + HF$$

$$Ca_5F(PO_4)_3 + 7\,H_3PO_4 \longrightarrow 5\,Ca(H_2PO_4)_2 + HF$$

The first reaction is complete in 5 – 20 min. Components of the rock, such as calcium fluoride, calcium carbonate, silica, iron, and aluminum, all affect reaction rate.

Silica reacts with hydrogen fluoride from the above reaction to give fluosilicic acid, which dissociates to silicon tetrafluoride:

$$6\,HF + SiO_2 \longrightarrow H_2SiF_6 + 2\,H_2O$$

$$H_2SiF_6 \longrightarrow SiF_4(g) + 2\,HF$$

Phosphate rock contains 2 – 5 % fluorine, of which 10 – 30 % is rapidly evolved as silicon tetrafluoride during acidulation. The SiF_4-enriched off-gas is used for the production of fluosilicic acid (→ Fluorine Compounds, Inorganic, Chap. 5.2.; see also Section 8.1.3). The rest of the fluorine remains in the superphosphate product as unreacted calcium fluoride, water-soluble calcium silicofluoride, or free fluosilicic acid.

Practical experience shows that phosphates rich in carbonate are acidulated more quickly and evolve more silicon tetrafluoride. The silicon tetrafluoride yield increases with higher sulfuric acid concentration, higher temperature, more finely ground rock, and longer mixing time. However, some of these conditions are harmful for the production of a good superphosphate.

The effects of particle size and acid concentration on the reaction rate for Morocco rock have been studied in the laboratory [30]. In the example shown in Figure 13 the free sulfuric acid is consumed after 60 min. The concentration of free phosphoric acid reaches a maximum of ca. 58 %. After 1 h, approximately 80 % of the phosphate is water-soluble, about 70 % of this being free phosphoric acid. The amount of water-soluble phosphate increases to 92 % after one week and to 93 % after three weeks. At this time, 14 % is free phosphoric acid (corresponding to 3 % P_2O_5 in superphosphate).

Figure 13. Reaction of Morocco phosphate rock with 76 % sulfuric acid

On a technical scale the mixture goes to storage for curing (i.e., complete reaction) after 0.5 – 2 h. The mixture solidifies to form a gel consisting of colloidal MCP and containing anhy-

drous calcium sulfate crystals. The gel structure gives the fresh superphosphate a high plasticity. Superphosphate becomes fluid under pressure. These properties make handling difficult but facilitate granulation.

With increasing storage time and decreasing content of free acid, the gel structure becomes crystalline and plasticity decreases.

Byproducts. Superphosphate contains anhydrous calcium sulfate (gypsum). Small amounts of the dihydrate occur after prolonged storage when the content of free acid is very low. Hydration of calcium sulfate is inhibited strongly in the highly viscous aqueous phase. The stability limit for $CaSO_4 \cdot 2\,H_2O$ is reached rather early because hydration results in concentration of the liquid phase (Fig. 14).

Figure 14. Different forms of gypsum in superphosphate [31]

When the concentration of free phosphoric acid decreases below a certain limit, citrate-soluble DCP is formed:

$$Ca(H_2PO_4)_2 \rightleftharpoons CaHPO_4 + H_3PO_4$$

Formation of DCP can be reduced or avoided by the use of more concentrated acid or by drying the superphosphate product to increase the acid concentration in the liquid phase.

The iron and aluminum compounds in phosphate rock can form water-soluble compounds during acidulation, but they react to produce water-insoluble compounds when the amount of free acid is reduced.

8.1.2. Production [31]

The production of superphosphate consists of grinding the phosphate rock, mixing the reaction components, acidulation, curing in a den, transportation to storage for final curing, and granulation or further processing to compound fertilizers.

Grinding Phosphate Rock. Phosphate rock is ground before being mixed with sulfuric acid. The particle size depends on different factors: reactive phosphate rock can be ground more coarsely; the use of concentrated sulfuric acid demands a more finely ground rock. Modern continuous superphosphate plants with a short curing time also need a more finely ground rock, in general >90 % through 100 mesh (<150 μm).

Batch Processes. Up to about 1970 the batch process dominated because it allowed a more accurate feed of phosphate rock and sulfuric acid. Mixing time could also be adjusted to give a good quality product. The primary disadvantage was the need for manual cleaning.

Examples of batch processes are the Beskow den process (developed in Europe, Fig. 15) and the Sturtevant den process (developed in the United States).

Figure 15. Beskow den batchwise superphosphate process a) Reaction vat; b) Rotating cutter for removing superphosphate product

Beskow Den Process. The chamber floor is mounted on rollers. The curved back wall of the chamber is fixed to the floor and the side walls can be folded away. The front wall consists of two folding doors that are opened prior to emptying the chamber. The chamber wagon is then

pulled toward a fixed revolving cutter equipped with vertical knives that scrape off the superphosphate. Beskow wagons can hold 50 – 100 t of product. Mixing of the components must be rapid and thorough so that the mixture remains thin enough to run over the surface of the chamber contents.

Figure 16. The TVA mixer for superphosphate production

Figure 17. Moritz – Standaert superphosphate den process [32]
a) Cutter; b) Inner cylinder; c) Outer cylinder; d) Stationary bottom; e) Superphosphate outlet

Continuous Processes. Continuous processes are now dominant. Sulfuric acid is measured and controlled by magnetic flow meters. Different types of paddle mixers are used.

The *Tennessee Valley Authority (TVA)* has developed a simple cone mixer (Fig. 16) without moving parts. The acid is fed in by two to eight tangential nozzles, and phosphate rock is fed into the center of the swirling acid. This mixer is usually combined with a den belt and used mainly to produce triple superphosphate.

The *Moritz – Standaert den process* was often used in Western Europe and involves a movable, circular den (Fig. 17).

Another common European process is the *Broadfield den process* (Fig. 18). The Broadfield den consists of a slat conveyor mounted on rollers, with a long stationary box over it and a revolving cutter at the end. A variable-speed drive is used for the conveyor, giving a retention time of ca. 30 min [32]. A similar process was developed by *Nordengren*. Here, a reaction chamber is built into the top of the den to allow sufficient time for solidification of the superphosphate mixture [32].

Figure 18. Broadfield den process
a) Den; b) Cutter

In the *Kuhlmann den process* (Fig. 19), denning is accomplished by transporting a thin layer of the mixture on a long, flexible belt conveyor. The den is troughed for more than half its length to form its own side walls. A hood is provided to collect the off-gas [32].

Figure 19. Kuhlmann den superphosphate process
a) Hood; b) Cutter

A high-speed mixer used in combination with a den has been developed by *Agrimont* in Italy (Fig. 20). The very brief and intense mixing gives a short curing time and a high-quality superphosphate.

8.1.3. Fluorine Recovery [33]

Off-gases from the mixer and the den contain air, steam, carbon dioxide, and silicon tetrafluoride. The fluorine content is normally 0.5 –2 vol % but depends on process conditions and air flow.

When the off-gases are washed in scrubbers, silicon tetrafluoride reacts with water to form fluosilicic acid [*16961-83-4*], which is used as a commercial product (→ Fluorine Compounds, Inorganic, Chap. 5.2.):

$$3\,SiF_4 + 2\,H_2O \longrightarrow 2\,H_2SiF_6 + SiO_2$$

The silica is at first colloidal and therefore impossible to filter. It solidifies in an uncontrollable fashion.

The first cleaning units consisted of Venturi scrubbers and spinning disk scrubbers (Fig. 21). Hydro Supra has now developed a process giving clean fluosilicic acid (20 – 25 % H_2SiF_6 containing <100 mg of P_2O_5 per liter) suitable as a raw material for the production of aluminum fluoride from alumina (Fig. 22). The first stage is a Venturi scrubber (a), where solid P_2O_5 is absorbed. The fluosilicic acid produced in absorption towers (b) is fed to an aging tank (c) where silica particles grow. The silica particles are then filtered from the product acid (d) and mixed with the Venturi liquid (e) before being recycled to the process.

8.1.4. Granulation [34]

After 3 – 6 weeks storage, superphosphate may be crushed, bagged, and sold as powder superphosphate. The product is dusty and has a high caking tendency. This disadvantage can be avoided by granulation to 2 – 5-mm particles. Granulated superphosphates have been on the market since 1950 and now account for all commercial superphosphates in the Western world.

Run-of-pile powder superphosphate is granulated with steam or water in a drum (length 6 – 12 m, diameter 3 – 5 m). Another possibility is use of a pan granulator with a diameter of 3 – 5 m.

Freshly produced superphosphate is more easily granulated but may cause handling problems due to its plasticity (see Section 8.1.1).

After granulation, the superphosphate product is dried in rotating drums, cooled in a similar drum, and screened to a product size of 2 – 5 mm. The fine undersize particles are directly recirculated to the granulator, whereas the coarse oversize particles are crushed before recycling. The final product can be cooled further before storage and dispatch.

Dust formed in the dryer, the cooler, the screens, and the crushers is separated from the off-gases in dust-collecting equipment.

8.2. Triple Superphosphate [35]

Single superphosphate contains up to 50 % calcium sulfate. If sulfuric acid is replaced by phosphoric acid for acidulation of phosphate rock, triple superphosphate is produced with a higher content of MCP and without calcium sulfate. The principal chemical reaction is

$$Ca_5F(PO_4)_3 + 7\,H_3PO_4 \longrightarrow 5\,Ca(H_2PO_4)_2 + HF$$

Triple superphosphate has similar properties to single superphosphate but lower plasticity. Optimal process conditions and product quality are reached with a phosphoric acid concentration of 50 – 54 % P_2O_5. The same equipment is used as for single superphosphate production (see Section 8.1.2). However, the mixing time is shorter, due to faster chemical reaction (10 – 20 s). The reaction heat is one-third that for single superphosphate. The same temperature (80 – 100 °C) is reached, but less water vapor and silicon tetrafluoride are evolved.

Granulation based on run-of-pile powder triple superphosphate is similar to granulation of single superphosphate (Section 8.1.4).

A slurry granulation process can also be used. The Dorr – Oliver process route is usually employed. Phosphoric acid (40 % P_2O_5) is mixed with ground phosphate rock in a large tank reactor with a retention time of 3 – 5 h. The slurry is then pumped directly to a granulator. As in the run-of-pile route, the granulation process consists of drying, crushing, recycling, and cooling.

8.3. Double Superphosphate

In the production of double superphosphate, phosphate rock is treated with a mixture of sulfuric and phosphoric acids. The phosphate content of double (enriched) superphosphate thus corresponds to mixtures of single superphosphate and triple superphosphate containing 18 – 45 % P_2O_5. The product is used mainly as an intermediate for PK products [36].

By mixing sulfuric and phosphoric acids, more dilute phosphoric acid can be used. This reduces the energy requirement for concentration of phosphoric acid. The balance between sulfuric acid and phosphoric acid depends on the acid concentration [32].

8.4. PK Fertilizers [36]

Triple superphosphate or double superphosphate can be granulated together with potassium chloride, potassium sulfate, and magnesium sulfate. The granulation process is the same as for single superphosphate (see Section 8.1.4), but chloride salts release hydrogen chloride gas during drying. The hydrogen chloride gas must be recovered in a scrubber.

The PK fertilizers are normally applied in the fall.

9. Ammonium Phosphates

For further details of ammonium phosphates, see → Phosphoric Acid and Phosphates.

9.1. Fertilizer Grades and Applications

Fertilizer-grade ammonium phosphates are normally produced from nonpurified wet process phosphoric acid (WPPA, or the so-called sulfur route) and consequently have a purity of only 70 – 85 %. In spite of relatively large deviations from the stoichiometric N/P ratio of the pure products, in the fertilizer grade they are called monoammonium phosphate (MAP), diammonium phosphate (DAP), and ammonium polyphosphate (APP). Triammonium phosphate, $(NH_4)_3PO_4$, has no significance as a fertilizer because it is unstable at 20 °C.

The nutrient content of solid ammonium phosphate fertilizers depends greatly on the quality of the phosphoric acid (Table 2).

Table 2. Composition of ammonium phosphate fertilizers

Type	N, wt %	P_2O_5, wt %
MAP from fertilizer acid	10 – 12	57 – 48
MAP from purified acid	12	61
DAP from fertilizer acid	16 – 18	48 – 46
DAP from purified acid	21	53

Granular MAP and DAP are used as straight fertilizers or applied after mechanical blending with other granular fertilizers (bulk blending). Ammonium phosphate salts are also formed in situ or mixed into processes for the production of compound NP or NPK fertilizers from phosphoric acid or nitrophosphates.

Solid MAP is used extensively in the United States for the manufacture of suspension fertilizers (see → Fertilizers, Chap. 3.2.3.).

Ammonium polyphosphates are normally a constituent of liquid fertilizers (see → Fertilizers, Chap. 3.2.2.1.). The solid products were also expected to have a very important potential in connection with their high plant nutrient value and other special features, but in practice this did not turn out to be true. Only small quantities of solid products have been produced with a polyphosphate content up to 25 % of the ammonium phosphate [37], [38].

Pure MAP and DAP are used as fertilizers in irrigated greenhouses (completely water-soluble compounds).

9.2. Production

For a long time solid ammonium phosphate fertilizers were produced only in granular form in an integrated neutralization – granulation process [39]. This is still the case for DAP, but since the mid-1960s, considerable capacity has existed for producing MAP in powder form. This product is used as a relatively concentrated, low-cost intermediate for compound-fertilizer manufacture.

Crystallization processes for technically pure ammonium phosphates are not described here.

The high ammonia vapor pressure of DAP has important consequences for its industrial production. The same applies to the pronounced maximum solubility of a mixture of MAP and DAP at an N/P molar ratio of ca. 1.4 [40] (eutectic mixture containing 17 % water, *fp* 110 °C). The point at which the borderline in Figure 7 crosses the 110 °C isotherm corresponds to the composition 46 % MAP, 37 % DAP, and 17 % H_2O. This is equal to an N/P molar ratio of 1.4 (Fig. 6).

9.2.1. Ammonium Phosphate Powder

MAP Powder. The processes used for the production of MAP powder (particle size 0.1 – 1.5 mm) are relatively simple. All processes are claimed to give good storage, handling, and granulation properties when used for the manufacture of MAP, DAP, or other NP/NPK compound fertilizers.

In the *PhoSAI process* of Scottish Agricultural Industries [41] (Fig. 23), ammonia reacts with phosphoric acid (minimum concentration 42 % P_2O_5) in a stirred-tank reactor (d) to produce a slurry with an N/P ratio of 1.4 (point of maximum solubility) under atmospheric pressure. The slurry flows to a pin mixer (e) in which the N/P ratio is brought back to ca. 1 by the addition of more concentrated phosphoric acid. During this step the solubility decreases and more water vaporizes due to the heats of reaction and crystallization. A solid product is formed that typically contains 6 – 8 % moisture. This is screened (f) and the oversize particles are ground, after which the product can be stored without further treatment.

Figure 23. PhoSAI process for nongranular MAP
a) Fan; b) Separator; c) Gas scrubber; d) Reactor; e) Pin mixer; f) Screen; g) Oversize crusher

In the *Minifos process* [42] of Fisons (now Hydro Fertilizers), ammonia and phosphoric acid (45 – 54 % P_2O_5) react (Fig. 24, b) at 0.21 MPa to give an N/P ratio of 1. The liquid product is flash-sprayed in a natural-draught tower (c), where the droplets solidify to form a powder with 6 – 8 % residual moisture.

Figure 24. Hydro Minifos process for MAP powder
a) Ammonia evaporator; b) Pressure reactor; c) Spray tower

Alternative processes based on the use of a pipe reactor instead of a tank reactor were developed by Gardinier S.A. [39], Swift Agricultural & Chemical Corporation (Fig. 25) [43], and ERT – Espindesa [44], [45]. Product humidity is reported to be as low as 2 %, which results in less caking.

Figure 25. Swift process for MAP powder
a) Pipe reactor; b) Surge tank; c) MAP tower; d) Discharge scraper; e) Scrubber system; f) Fan

More recent MAP powder plants are based on the use of pipe reactors (including those designed by Hydro Fertilizers).

Considerable quantities of MAP powder are produced from "sludge acids" from phosphoric acid clarification with solids contents up to 20 %.

Figure 26. ERT – Espindesa process for DAP powder

DAP Powder. Based on the favorable results obtained with a pipe reactor for MAP powder manufacture, ERT – Espindesa experimented with the production of DAP powder [44], [45] (Fig. 26). The DAP product has a remarkably high water- and citrate-soluble P_2O_5 content, probably due to the short residence time in the reactor, which does not yield the insoluble

salts that are normally formed in long-retention-time DAP plants. The same effect has been observed with MAP formed in a pipe reactor.

9.2.2. Granular Ammonium Phosphates

Since the 1960s, granular ammonium phosphates have belonged to some of the most important fertilizer products [46]. They are applied directly or used as intermediates in bulk blends and for the manufacture of compound fertilizers. More than five times as much DAP is produced as MAP. Since the beginning of large-scale production in the 1930s, considerable developments have been made to optimize raw material and energy efficiencies, to reduce the capital cost of the plants, to improve their reliability, and make them more environmentally friendly.

Granular ammonium phosphate plants consist of a wet and a dry section, the dry section being a granulation loop (→ Fertilizers, Chap. 5.).

Granular DAP. In the 1950s the *Dorr – Oliver process* was most commonly used. Phosphoric acid and ammonia react in two or three vessels in series at atmospheric pressure under conditions that take advantage of solubility and vapor pressure properties.

Initially, three reactor vessels were used. Neutralization to MAP was carried out in the first. In the second, more ammonia was injected until ca. 80 % DAP was formed. Final ammoniation occurred in the third reactor but was later carried out in the blunger (pugmill) of the granulation loop. Because of the low solubility of DAP the process must be run with a high slurry water content to maintain fluidity. High recycle ratios are also required to avoid overgranulation in the blunger where the slurry and recycle are mixed to give a moist granulate containing 4 – 6 % water. Typically, these recycle ratios are between 11 : 1 and 8 : 1, depending on where final ammoniation occurs. The granules are dried in a concurrent rotary dryer and screened. The fines, smaller granules, and broken oversize particles are recycled to the pugmill. Cooling of the on-size product (1.5 – 3 mm) is not essential but is recommended to minimize loss of ammonia and ensure good storage stability.

Off-gases from reactors, granulator, and dryer are scrubbed with filter-strength (28 % P_2O_5) acid. Stronger acid (40 – 52 % P_2O_5) is used in the reactor section.

In the early 1960s the TVA [47], [48] (Fig. 27) introduced a modified process that became very

Figure 28. Hydro Fertilizers DAP granulation process with pressure reactor
a) Tail-gas scrubber; b) Ammonia scrubber; c) Bag filter; d) Pressure reactor; e) Granulator; f) Dryer; g) Cyclone; h) Screens; i) Crusher; j) Fluidized-bed cooler; k), l) Surge tanks

popular because the recycle ratio dropped to ca. 5:1.

Acid reacts with ammonia in a preneutralizer (b) where the N/P ratio is controlled at about 1.4. The heat of reaction raises the slurry temperature to the boiling point (ca. 115 °C) and evaporates water. The hot slurry contains 15 – 20 wt % water and is pumped to a rotary drum granulator (d) where it is sprayed on a relatively thick bed of recycled material. Additional ammonia is sparged underneath this bed to increase the molar ratio to 2.0. Additional heat is generated, resulting in the evaporation of more moisture. The decrease in solubility obtained in going from a molar ratio of 1.4 to 2.0 assists granulation.

Further reduction of the recycle ratio (e.g., to 4:1) is attained by carrying out preneutralization to an N/P ratio of 1.4 in a pressure reactor (Hydro Fertilizers) [47], [49] operating at 0.1 MPa overpressure; so that the boiling point of the reaction mixture is elevated by ca. 20 °C compared to operation at atmospheric pressure (Fig. 28). Thus, the steep temperature dependence of the solubility of ammonium phosphate in water allows operation at a lower water content while maintaining the ammonium phosphate in solution. The amount of water fed to the granulator is therefore minimized.

In an attempt to further simplify DAP plants and reduce the recycle ratio, TVA, CROS S.A., and ERT – Espindesa have tried to use pipe reactors [50] (also called T reactors or pipe-cross reactors) directly releasing slurry in the rotary granulator, instead of applying a preneutralization tank.

CROS and ERT – Espindesa [51] report successful operation, but experiences in several U.S. plants were disappointing because of high heat input in the granulator.

Figure 29. The AZF dual pipe process for granulated DAP
a, b) Pipe reactors; c) Granulator; d) Dryer – cooler; e) Screen; f) Mill

CdF – Chimie AZF [51–53] originally had the same experience, but succeeded by introducing a second pipe reactor spraying into the dryer (Fig. 29).

Approximately half of the phosphoric acid is fed to a pipe reactor (a) that operates at N/P = 1.4 and releases its product into the granulator (c). The remaining acid is fed into a second pipe reactor (b) at N/P = 1.1 that sprays into the dryer (d). Extra ammonia is introduced underneath the rolling bed in the rotary drum granulator.

The pipe reactor (b) in the dryer produces MAP powder. Part of it is carried away into the cyclones of the dedusting loop; the remainder crystallizes on the DAP product.

The recycle ratio of this process is lower than with a conventional preneutralizer; fuel consumption of the dryer is also reduced.

Granular MAP. Granular MAP is produced in the same types of plants as DAP. The most common process is the TVA, with a preneutralizer and rotary drum ammoniation (Fig. 27). The preneutralizer is operated at an N/P ratio of 0.6, again a point of high solubility, and more ammonia is added in the granulator to increase the molar ratio to 1.0.

In contrast to DAP production, ammonia recovery by acid scrubbing is not necessary, but all off-gases are scrubbed to recover dust and fumes. Granular plants can thus be simpler, but most units are designed so that both products can be made in the same plant.

The pipe reactor processes [43] have been very successful in MAP production. They operate with a very slight ammonia loss, and little or no additional heat is required for drying. In some plants, preneutralizers have been replaced by pipe reactors.

9.2.3. Off-Gas Treatment

An essential process step in all ammonium phosphate plants is scrubbing of the off-gas. The preneutralizer and pipe reactors give ammonia slip due to vapor pressure and "mechanical losses" caused by imperfect mixing. Absorption of ammonia in the rotary drum or blunger is not 100 %; ammonia is released from DAP in the dryer and cooler due to its high vapor pressure. Off-gases may also contain dust and ammonium fluoride aerosols.

In an environmentally friendly plant, all off-gases are treated [54]. In DAP plants, relatively large quantities of ammonia must be recovered. This is normally done by using filter-strength (28 % P_2O_5) phosphoric acid, which is subsequently sent to the preneutralizer or pipe reactor. Dilute sulfuric acid scrubbing may also be employed. Sulfuric acid can also increase the N/P ratio of the product.

Passage of large quantities of air through scrubbers that operate on wet process phosphoric acid results in the stripping of considerable quantities of fluorine-containing gases, which must be absorbed in tail-gas scrubbers. In the production of granular MAP, off-gas treatment is simpler due to the lower ammonia slip.

In modern powder MAP plants, entrained dust is recovered in a scrubber with circulating process water that is sent to the reactor section.

10. Compound Fertilizers by the Sulfur Route

Compound fertilizers (also called complex or mixed fertilizers) contain more than one plant nutrient element. They may be ternary (N + P + K) or binary (N + P, P + K, or N + K). They may also contain considerable quantities of magnesium or trace elements.

The reason for applying compound fertilizer is convenience: farmers no longer have to apply several straight (single-element) fertilizers separately. However, even if compound fertilizers are used, nitrogen is often still applied separately because supplementary dressings of nitrogen may be needed during the growing season. Also, some straight nitrogen materials (e.g., urea – ammonium nitrate solution) are sometimes considerably cheaper than the same amount of nitrogen in compound fertilizers.

The first compound fertilizers were powder mixtures (e.g., of ammonium sulfate, superphosphate, and potash). In the 1930s, producers began to ammoniate superphosphate and thus introduced a cheap form of nitrogen, while improving the physical properties of the superphosphate.

To lower transportation costs, higher-grade products were used, which, however, caused se-

rious caking problems. Increased mechanical application called for free-flowing material, and in the 1950s granulation therefore started to become popular.

Figure 30. Typical plant for granulation of dry materials a) Rotary drum granulator; b) Dryer; c) Cyclone; d) Screen; e) Crusher; f) Cooler; g) Coating drum

The concentration of compound fertilizers increased as single superphosphate was replaced by triple superphosphate, and ammonium nitrate or urea replaced ammonium sulfate. Later, even higher grades were attained by using phosphoric acid and ammonia. Production was no longer a simple, mainly mechanical operation, but rather a complex chemical processing operation.

Figure 31. Relationship of temperature and water content for the granulation of fertilizers

Bulk blends (see → Fertilizers, Chap. 5.5.) became popular in some countries as a method by which a local dealer with a simple mixing plant could supply whatever mix the farmer needed. Granular materials with an approximately equal size distribution (e.g., DAP, compacted potassium chloride, ammonium nitrate, or urea) are used. These compounds are shipped in bulk to the blenders who offer prescription mixing, custom application, and other services to the farmers.

Dry mixing of nongranular materials is no longer used and therefore not described here.

10.1. Granulation of Mixtures of Dry Materials

Agglomeration with Steam or Water. Mixtures of dry powders or ground components can be granulated by agglomeration with the aid of steam or water.

Several devices are used, but rotary drum granulation is the most popular method (Fig. 30).

Incoming materials are screened to remove coarse lumps, which are crushed. The materials are fed in by batchwise weighing or with continuous weighing belts. In the rotary drum granulator (a) the mixture of recycle and raw materials is adjusted for agglomeration by injecting steam underneath the bed and, if necessary, by spraying water on top. Granulation is performed so that optimum quantities of on-size granules (in Europe mostly 2 – 4 mm, in the United States normally 1 – 3.3 mm) are formed, with a minimum of oversize particles [55]. Obtaining more than 60 – 70 % of the product in the desired size range is difficult, but the recycle ratio for such operations is normally $<1:1$. Optimum granulation is obtained at a defined "liquid-phase" content (i.e., the water content plus the salts that dissolve in this amount of water). Because the solubility of salts increases with temperature, a higher temperature means that less water is required (Fig. 31). Although such a curve can be used to predict the optimum point at which granulation occurs, it does not describe granulation efficiency, which depends on the degree of plasticity of the mixture. Pure inorganic salts (e.g., KCl, NH_4NO_3) have little plasticity and are relatively difficult to granulate. In contrast, fresh single superphosphate shows excellent agglomeration properties (see section 8.1.2). The binding tendency of ammonium phosphates is highly dependent on their impurity content [56].

Steam granulation is normally better than the use of water alone because the damp granules are hotter, have a lower moisture content, and, therefore dry more easily. The product is usually more dense and stronger. The curve shown in Figure 31 depends not only on the composition of the salt mix, but also on the physical properties of the raw materials. The particle size of the feed and the potash coating may affect binding ability [57].

After the granulator, the remainder of the plant is similar for all granulation processes (→ Fertilizers).

The grades produced in such a plant depend on the raw materials. The product can be very low in concentration (N-P_2O_5-K_2O = 9-9-9) if it is based on single superphosphate and ammonium sulfate, and very concentrated (19-19-19) if it is based on urea and nongranular MAP or DAP.

Compaction and Extrusion [58–62].
Roll compaction is described elsewhere (→ Fertilizers, Chap. 5.3.5.) and is used relatively little for the manufacture of compound fertilizers. Compaction is used for materials that are difficult to granulate (e.g., straight KCl). It operates at a low moisture level (0.5 – 1.5 %) and at ambient temperature, so that heat-sensitive materials can be admixed.

Particles made by compaction tend to be angular compared to the spherical granules produced by other shaping techniques. A further disadvantage is that the compacted particles may react with each other, resulting in disintegration.

10.2. Granulation of Dry Materials with Additives Producing Chemical Reactions

Chemically reacting materials can be introduced to increase the temperature. This allows granulation to proceed with a minimum water content and with reduced amounts of steam or water.

Ammoniation of superphosphates by injection of liquid or gaseous ammonia underneath the bed or by use of aqueous solutions of ammonium nitrate or urea containing free ammonia is such a technique. The ammonia initially neutralizes free acid in the superphosphate and then reacts with the water-soluble MCP to form non-water-soluble, but citrate-soluble P_2O_5 (mainly DCP) [63–65].

Whether the decrease in water-soluble P_2O_5 content is acceptable depends on farmers' requirements. The United Kingdom and The Netherlands traditionally prefer water-soluble P_2O_5, whereas in the United States, France, and Germany "available" P_2O_5 is fully accepted as an equally valuable plant nutrient.

When nongranular MAP is present in the formulation it is often beneficial in terms of improving the granulability of the material that is to be ammoniated in the granulator. This increases the solubility of the ammonium phosphate, and heat is generated due to the chemical reaction of ammonia with MAP.

If heat released during ammoniation of the superphosphate or MAP is insufficient, sulfuric or phosphoric acid and more ammonia can be added directly to the granulator [66]. The development of the continuous ammoniator granulator by TVA has been very important in this context [65], [67]; see → Fertilizers, Chap. 5.3.2. This technique has been used very successfully in the granulation of solid urea-based NPK grades [66].

The TVA process was subsequently extended with a preneutralizer [68], [69], a reactor in which a slurry is produced by reacting ammonia or ammoniating solution with sulfuric or phosphoric acid [70]. It is used for formulations in which the heat of reaction becomes too great for release in the granulator.

The preneutralizer operates at the optimum N/P ratio of 1.4 to minimize introduction of water. Preneutralizers have recently been replaced by pipe reactors, which allow direct release into the granulator of slurry or melt with an even lower water content. An alternative is to introduce all or part of the P_2O_5 in the form of MAP powder; the crystallizing ammonium nitrate solution then provides the necessary plasticity. For solid urea-based NPK grades the pipe reactor process is a viable method.

10.3. Slurry Granulation

In slurry granulation, all or most of the ingredients enter the granulation system in slurry form (Fig. 32). See also → Fertilizers, Chap. 5.2.

Figure 32. Slurry granulation in the production of NPK fertilizer
a) Preneutralizer; b) Blunger; c) Dryer; d) Screen; e) Cyclone; f) Scrubber; g) Cooler; h) Crusher; i) Cyclone; j) Coating drum

The slurry is usually manufactured by neutralization of nitric, phosphoric, or sulfuric acid–or mixtures of these acids–with ammonia. Potash may be added to the neutralized slurry before granulation or in the granulator. If potassium chloride is required, premixing with slurries containing ammonium nitrate is beneficial for product quality because the reaction

$$KCl + NH_4NO_3 \longrightarrow KNO_3 + NH_4Cl$$

is virtually complete before the product goes to storage.

The granulator may be of the rotary drum or pugmill (blunger) type (→ Fertilizers, Chap. 5.3.), and recycled material (fines, broken oversize, and part of the on-size) is added in a proportion that ensures good granulation efficiency.

If the preneutralizer is used only to produce ammonium phosphate, the slurry must contain 15 – 20 % water so that it remains sufficiently fluid even when operating at the optimum N/P molar ratio. This creates conditions of excessive fluidity in the granulator, particularly when high-concentration grades such as 17-17-17 or 23-23-0 are produced. Large amounts of recycle are therefore required to control granulation, particularly when ammonium nitrate is added in the form of a concentrated solution rather than a solid.

As in the manufacture of granular DAP or MAP (see Section 9.2.2), processes have been modified to reduce the recycle ratio and thus save energy and boost the capacity of existing units or save capital when constructing new units. Employment of a cooled recycle by positioning the screening units downstream from the cooler allows granulation to occur at lower temperature and thus higher water content (Fig. 31) [71].

In a plant that produces grades containing both ammonium nitrate and ammonium phosphate, the phosphoric and nitric acids can be neutralized separately or together (coneutralization). Although separately neutralized ammonium nitrate can be concentrated easily (e.g., up to 95 –98 %), the ammonium phosphate slurry still contains 15 –20 wt % water. However, addition of ammonium nitrate to the ammonium phosphate increases its fluidity which allows the water content of the slurry to be decreased [72], [73]. This is the reason why nitric and phosphoric acids are often coneutralized. The coneutralized liquor is pumped to the granulator, if necessary, after further evaporation.

Other techniques to reduce the recycle ratio include the use of a pressure reactor to increase the boiling point and thus increase the solubil-

ity of ammonium phosphate. Fluid slurries are therefore obtained at a low water content [74], [75].

A pipe reactor can also be used that operates at a higher temperature and a lower water content than the preneutralizer. The pipe discharges directly into the granulator. If the ventilation capacity is sufficient to remove all the process steam, the recyle requirement decreases [76]. Pipe reactors have been fitted in blungers [77], rotary drum granulators [76], [78], [79], dryers, or both in rotary drum granulators and dryers [80], [81].

The use of a relatively high recycle in a slurry granulation plant is not always a disadvantage [82], [83]. Granule formation takes place largely by layering. The water is on the outside of the granule which facilitates drying. Because only a small portion of the granules can be exported, the screening operation is not very critical and the size-distribution quality is good. Finally, plants operating with a high recycle ratio and where granulation is "water-balance controlled" are normally more stable than low-recycle granulation plants whose capacity is determined by granulation efficiency, which depends on fine tuning by the operators.

Figure 33. C & I – Girdler spherodizer granulation process for production of compound fertilizers
a) Air heater; b) Spherodizer granulator; c) Dust removal; d) Screen; e) Crusher; f) Surge tank

Slurry granulation is also carried out in spherodizers (Fig. 33) – spray-drum granulators in which granulation and drying are combined (→ Fertilizers, Chap. 5.2., → Fertilizers, Chap. 5.3.) [84].

Neutralized slurry containing all the potash is sprayed against a falling curtain of recycle solids produced by flights in a rotating drum. Hot air is blown in cocurrently with the slurry spray. Granulation takes place by layering. Granulation efficiency is high and the need for recycle is relatively low. The granules are well rounded, hard, and generally considered to be of excellent quality.

Drying during granulation is also a feature of the Scottish Agricultural Industries double-drum granulation process with a very large internal recycle (→ Fertilizers) [85]. Granulation and drying of compound fertilizers in fluidized-bed and spouted-bed equipment are also reported [86].

10.4. Melt Granulation

See also → Fertilizers.

Mixtures of ammonium nitrate and ammonium phosphate maintain their fluidity at very low moisture content provided the temperature is sufficiently high (Figs. 9 and 10). The concentrated melt can therefore be allowed to solidify and dry by the heat of crystallization.

If the acid is concentrated and/or preheated, the heat of neutralization may be sufficient to drive out all the water. If not, the N – P solution can be concentrated by using external heat in an evaporator. Removal of the water before granulation is thermally more efficient than using a conventional dryer. Hydro Fertilizers operated such a melt granulation plant for several years (Fig. 34) [87].

Another way to produce melts is to use a pipe reactor operating at high temperature [88]. The pipe produces virtually anhydrous melts, which are blown directly onto a cooled recycle bed in the granulator (Fig. 35).

Normally phosphoric-acid-containing solutions mixed with nitrates are not ammoniated in pipe reactors because chlorine and organic impurities may reduce the safety limits for ammonium nitrate explosion. The practical use of pipe reactors is thus limited to processing of either pure ammonium nitrate or ammonium phosphates and sulfates.

The TVA ran a demonstration plant in which 15 – 25 % of the P_2O_5 was condensed to nonorthophosphates, mainly pyrophosphates [89].

Figure 35. Pipe reactor – drum granulator process
a) Pipe reactor; b) Drum granulator; c) Dryer; d) Cooler; e) Screens; f) Crusher; g) Scrubber; h) Heater; i) Heat exchanger

Potassium salts and other solid raw materials can be added to the melts to produce NPK products.

Methods to form particles from melts include pan, pugmill, and rotary drum granulation, as well as prilling [90] and flaking.

In a conventional melt granulation loop, the recycle requirement is determined not by the water balance, but by the need to remove sufficient heat. The recycle ratio is so low that the plant will be "granulation-efficiency" controlled.

11. Compound Fertilizers by the Nitro Route

Nitrophosphates are nitrogen- and phosphate-containing fertilizers that are produced by digestion of phosphate rock with nitric acid. Examples of known production processes are the mixed acid and Odda processes.

The nitrophosphate process was invented by Erling B. Johnson of Odda, Norway [91] to avoid the diluting effect of the sulfate ion in superphosphate. The process had been developed to the commercial stage by the 1930s, and

Norsk Hydro introduced its own technology in 1938. However, not until the sulfur shortage in the early 1950s did nitrophosphates become of interest, and a number of variants of the process were developed [92][93][94].

Approximately 10 % of the world's phosphate fertilizers are produced by the nitrophosphate route.

11.1. Chemistry

The overall acidulation reaction is given by

$$Ca_5F(PO_4)_3 + 10\,HNO_3 \longrightarrow 5\,Ca(NO_3)_2 + 3\,H_3PO_4 + HF$$

The reaction is normally carried out with an excess of 10 – 20 % nitric acid [95], [96]; acid-insoluble materials in the phosphate rock may be partly removed.

Most nitrophosphate processes include removal of calcium nitrate from the solution to increase the nutrient content of the product, to avoid precipitation of water-insoluble DCP during neutralization and to obtain a product that meets thermal stability requirements for transportation.

Figure 36. Crystallization points for calcium nitrate in the digestion liquor (digestion of phosphate rock with nitric acid)

About 60 % of the calcium nitrate crystallizes at 20 °C and 80 – 85 % at −5 °C (Fig. 36) [97], [98]. Alternatively, calcium can be precipitated as calcium sulfate by addition of ammonium sulfate to the solution. If the reason for using the nitrophosphate process is to remain independent of a sulfur source, sulfur can be recycled in the Merseburg process:

$$CaSO_4 + 2\,NH_3 + CO_2 + H_2O \longrightarrow CaCO_3 + (NH_4)_2SO_4$$

Calcium can be precipitated as calcium carbonate with carbon dioxide:

$$Ca(NO_3)_2 + 2\,NH_3 + CO_2 + H_2O \longrightarrow CaCO_3 + 2\,NH_4NO_3$$

Care must be taken to suppress formation of tricalcium phosphate, which is citrate insoluble:

$$2\,CaHPO_4 + CaCO_3 \longrightarrow Ca_3(PO_4)_2 + H_2O + CO_2$$

Another nitrophosphate process is the ion-exchange method in which dissolved calcium ions are replaced by potassium ions from a potassium-loaded ion-exchange resin [99]. An advantage of this process is that the resulting phosphoric acid – potassium nitrate solution can be used for making chloride-free NPK fertilizers.

11.2. Product Specification

High-grade fertilizers containing 50 – 90 % water-soluble P_2O_5 are produced, depending on the amount of calcium removed. Citrate-soluble P_2O_5 accounts for 99 – 100 % of the total phosphorus. The N/P_2O_5 ratio obtained by the normal nitrophosphate route ranges from about 0.7 to 5.0 in actual plant operation. Above a ratio of 2, ammonium nitrate from external sources must be added. If no ammonium sulfate is added, ca. 55 – 60 % of the nitrogen is in the form of ammonium and 40 – 45 % in the form of nitrate.

Today's nitrophosphate products are of a quality comparable to those based on the sulfur route [100].

11.3. Nitrophosphate Process with Calcium Nitrate Crystallization (Hydro)

Norsk Hydro has carried out extensive research and development on nitrophosphate process technology. The principles of the Odda process have been retained, i.e., phosphate rock digestion and calcium nitrate crystallization.

The process consists of three main parts:

1) Mother liquor production (phosphoric acid with nitric acid, Fig. 37)
2) Production of prilled or granulated products
3) Conversion of calcium nitrate to ammonium nitrate and calcium carbonate

The calcium nitrate can also be processed to granulated calcium nitrate fertilizers.

Digestion. Phosphate rock is dissolved in an excess of 60 % nitric acid in two stirred-tank reactors in series (Fig. 37). Because of the heat of reaction, the digestion temperature increases to 50 – 70 °C.

The main reactions for phosphate rock containing silica, carbonates, and metal oxides are:

$$Ca_5F(PO_4)_3 + 10\,HNO_3 \longrightarrow 3\,H_3PO_4 + 5\,Ca(NO_3)_2 + HF$$

$$6\,HF + SiO_2 \xrightarrow{-2\,H_2O} H_2SiF_6 \rightleftharpoons SiF_4 + 2\,HF$$

$$YCO_3 + 2\,HNO_3 \longrightarrow Y(NO_3)_2 + CO_2 + H_2O$$
$$Y = Ca \text{ or } Mg$$

$$X_2O_3 + 6\,HNO_3 \longrightarrow 2\,X(NO_3)_3 + 3\,H_2O$$
$$X = Al \text{ or } Fe$$

Acidulation of phosphate rock liberates small amounts of nitrogen oxides (NO_x), water vapor, hydrogen fluoride, and silicon tetrafluoride. These gases are vented to a scrubbing system.

The amount of NO_x formed is highly dependent on the amount of iron, sufides, organic material, and other reducing agents in the rock. Urea is added to the first digester to reduce the amount of NO_x formed. No urea is found in the final product [101]. An antifoaming agent is also added to the first digester.

Some phosphate rocks contain large amounts of acid-insoluble material, which can be removed with sand traps or hydrocyclone (Fig. 37, d) systems. The insolubles are normally washed in a drum (e) and filtered on a belt before disposal.

Crystallization is accomplished by cooling. The digestion liquor is cooled and forms $Ca(NO_3)_2 \cdot 4\,H_2O$ crystals (Fig. 37, f). Crystallization begins at ca. 23 °C, and solubility decreases rapidly with decreasing temperature. The end temperature of the crystal slurry is adjusted (normally to 0 to −5 °C) to obtain the desired composition (CaO/P_2O_5 ratio) in the final product.

Crystallization is carried out batchwise to avoid buildup of deposits on the cooling coils. Cooling is performed by circulating cold ammonia – water solution through coils. Some of the heat removed is used to vaporize the ammonia required in the process. The rest of the heat load is removed by mechanical refrigeration or by cold water.

Calcium Nitrate Filtration. The crystal slurry enters a feed tank and is fed continuously to filters (Fig. 37, g), where $Ca(NO_3)_2 \cdot 4\,H_2O$ crystals are separated from the mother liquor. In a second filter stage, the crystals are washed with nitric acid and water. The wash acid is returned to the first digester.

The mother liquor is pumped to the neutralizers. The calcium nitrate crystals are flushed to a melting tank (i) before being processed in the conversion plant or to calcium nitrate fertilizers.

Neutralization. The mother liquor contains phosphoric acid, nitric acid, some hydrofluoric acid, dissolved calcium and magnesium nitrates, small amounts of dissolved impurities (e.g., iron, aluminum, silicon), and suspended insoluble particles (e.g., quartz). Neutralization takes place in one or two reactors by addition of gaseous ammonia under strict pH control (Fig. 38, a). Nitric acid or ammonium nitrate solution is added to adjust the N/P_2O_5 ratio in the final product.

When the acids are neutralized with ammonia, calcium and most of the dissolved impurities precipitate as fluorides and phosphates:

$$Ca(NO_3)_2 + 2\,HF + 2\,NH_3 \longrightarrow 2\,NH_4NO_3 + CaF_2$$

$$Ca(NO_3)_2 + H_3PO_4 + 2\,NH_3 \longrightarrow 2\,NH_4NO_3 + CaHPO_4$$

Ammonium nitrate and ammonium phosphates remain in solution. Ammonium nitrate solution is added to give the desired N/P_2O_5 ratio.

Due to the heat of reaction, water and ammonia are evolved during operation. Ammonia is normally recovered as ammonium nitrate in the off-gas treatment system.

Nitrophosphate Evaporation. The nitrophosphate liquor from the neutralizers is concentrated in two stages in evaporators under reduced pressure (Fig. 38, b). The water content in the concentrated slurry is ca. 2.5 % for granulation and 0.5 % for prilling.

Figure 37. Nitrophosphate mother liquor (NP acid) production

Figure 38. Nitrophosphate neutralization, evaporation, and prilling
a) Neutralization; b) Nitrophosphate evaporator; c) Mixing vessel; d) Prilling tower; e) Screen; f) Mill; g) Cooler; h) Coating drum

During evaporation, some ammonia escapes with the water vapor. Ammonia is recovered by scrubbing with acidic ammonium nitrate solution or by indirect condensation and subsequent stripping from the condensate. Prior to ammonia recovery, fluorine is removed from the vapor by scrubbing to avoid plugging and corrosion.

Mixing and Prilling/Granulation. The concentrated nitrophosphate liquor flows by gravity to the mixing – prilling section (Fig. 38, c, d). For the production of NPK, concentrated nitrophosphate liquor is mixed with potassium chloride (or sulfate) in a high-speed mixer. Recycled material from the dry handling

system containing dust, crushed oversize particles, and fines is also added to the mixer.

In the prilling process [102–104] the mixer overflows to a rotating prill bucket from which the slurry is sprayed into the prill tower. Fans at the top of the tower cause cold air to flow countercurrent to the droplets and result in solidification. The solid prills fall onto a rotating tower bottom and are scraped toward the edge by a scraper. The percentage of off-size normally varies between 10 and 20 %.

The granulation process is similar to that presented for the sulfur route (see Figs. 31, 32, 33, 34).

After screening (e), coarse particles are crushed (f) and recycled, together with fine particles, to the mixer. The product flows to a rotating drum or a fluidized-bed cooler (g) to adjust product temperature before being sent to storage. Solid and liquid anticaking agents are added to the product in the coating drum (h).

Salt Preparation. The primary steps of salt preparation are weighing, drying, and screening. The main salts added to the process are kieserite, dolomite, potassium chloride, and potassium sulfate. These fairly pure salts contain only small quantities of other metals or insolubles.

Figure 39. Conversion of calcium nitrate
a) Absorption; b) Conversion; c) Cooler; d) Filtration; e) Evaporation
AN = ammonium nitrate; CAN = calcium ammonium nitrate; CN = calcium nitrate

Calcium Nitrate Conversion. The calcium nitrate byproduct can be either used for the production of calcium nitrate fertilizers or converted into ammonium nitrate solution and calcium carbonate [105–108].

Calcium nitrate crystals from the filters are melted before being reacted with ammonium carbonate solution. The slurry is filtered on a vacuum filter, and the filter cake is washed with water.

In the Norsk Hydro process (Fig. 39), absorption of ammonia and carbon dioxide, and subsequent precipitation of calcium carbonate, take place in separate units. Ammonium carbonate is formed by reaction of gaseous ammonia and carbon dioxide in a recirculated stream of 60 % ammonium nitrate solution.

Because of the heat of reaction, external coolers (c) are installed to control the absorber temperature and to reach the desired temperature for the ammonium carbonate solution entering the conversion reactor.

Precipitation of calcium carbonate takes place in the conversion reactor (b):

$$Ca(NO_3)_2 + (NH_4)_2CO_3 \longrightarrow 2\,NH_4NO_3 + CaCO_3$$

To ensure complete precipitation the reactor is operated with a slight excess of carbon dioxide. Because the heat of reaction is relatively low, no cooling is required.

The reactor slurry can be filtered on a rotary vacuum filter or a belt filter (d); the filter cake should be washed with hot water. The calcium carbonate is used both for technical and agricultural purposes. Another alternative is to make calcium ammonium nitrate fertilizer (28 % N).

Because the ammonium nitrate solution contains a slight excess of ammonia, it is neutralized with nitric acid prior to evaporation (e).

11.4. Nitro Process with Calcium Nitrate Crystallization (BASF)

The Odda process has been used by BASF since 1953 at Ludwigshafen and until recently at its subsidiary in Köln.

The company designed and built a new 700 000-t/a plant at Antwerp, which went into operation in 1985; BASF now offers the process for license. Contracts have been awarded to Agrolinz (Austria) and Bharuch (India).

The principles of the BASF process (Fig. 40) are similar to those of the Norsk Hydro process; the following description focuses on the

Figure 40. The BASF granulation process for production of NPK fertilizers
a) Neutralization; b) NPK slurry; c) Granulation; d) Dryer; e) Hot screen; f) Cooling; g) Crusher; h) Cold screen; i) Finishing

main features specific to the BASF process [98], [109].

Digestion is carried out in a cascade of reactors. The temperature must be kept above 68 °C to ensure complete acidulation and below 72 °C to prevent corrosion. Residence time is 2 h. Foaming is usually controlled by specially designed stirrers, but antifoaming agents may be required. Only rock particles larger than 4 mm–usually <10 % of the total–require crushing.

The process employs sedimentary rocks containing 68 – 75 % tricalcium phosphate in the form of fluorapatite.

Crystallization and Separation of Calcium Nitrate. Crystallization is carried out in tanks with integral cooling coils. The cooling medium is chilled brine. In more recent systems the crystallizers are operated batchwise, but the cooling coils are connected in series.

The following conditions should be satisfied to achieve optimum crystal separation:

1) High separation efficiency with regard to $Ca(NO_3)_2 \cdot 4\,H_2O$ and nitrophosphate solution
2) Low sensitivity to changing process conditions
3) Minimal costs for operation, maintenance, and repair

The shear centrifuges used in older plants operate in conjunction with downstream hydrocyclones and only partially meet these requirements. The centrifuges are subjected to a great deal of wear and are extremely sensitive to the penetration of sand from the digestion stages. The screen slots must be wide; they allow large amounts of salt to slip through, which cannot be recovered adequately with downstream hydrocyclones. A sharp boundary between the separation zone and the washing zone cannot be achieved. Belt filters are therefore used in new plants and meet the above-mentioned requirements more satisfactorily.

Neutralization and Evaporation. The N/P_2O_5 ratio of the nitrophosphate solution from the mother liquor is adjusted with concentrated ammonium nitrate obtained by the conversion of separated calcium nitrate. The slurry is then ammoniated in two stages at 120 – 130 °C. Overammoniation, which would result in ammonia loss and cause reversion of phosphate to a citrate-insoluble form, is prevented by an automatic pH monitor.

If necessary, the slurry is evaporated at atmospheric pressure in heated, single-stage evaporators with forced circulation.

Granulation. Final correction of the N/P ratio and incorporation of the potassium salt are

carried out in mixers. The slurry is then sprayed into a drum granulator (spherodizer) or a pugmill granulator. The spherodizer type of drum operates with slurries containing 15 – 20 % water, and only a small amount of material is recycled. In standard drum or pugmill units a water content <8 % is required, and the granulation and drying units are separate. Production also involves screening, crushing, cooling, and coating units.

Calcium Nitrate Conversion. As in the Norsk Hydro process (see page 34), calcium nitrate conversion is carried out by treatment with ammonium carbonate. An ammonium carbonate solution is made by absorbing carbon dioxide and ammonia into ammonium nitrate solution. A belt filter is again used for separation. The calcium carbonate either can be used for making lime ammonium nitrate fertilizer or can be used in the cement industry. The ammonium nitrate solution passes through pressure filters to remove any calcium carbonate present due to malfunction upstream; it is then concentrated in steam-heated evaporators.

11.5. Nitro Process with Ion Exchange (Kemira Superfos)

The ion-exchange process (Fig. 41) permits the production of high-grade, chloride-free NPK fertilizers based on the cheapest possible raw materials [99].

Figure 41. Kemira Superfos ion-exchange NPK process

Acidulation of calcium phosphate with nitric acid gives a solution containing calcium ions, phosphoric acid, and nitrate ions:

$$Ca_5F(PO_4)_3 + 10\,HNO_3 \longrightarrow 5\,Ca^{2+} + 3\,H_3PO_4 + 10\,NO_3^- + HF$$

If the acidulated solution is exposed to a potassium-loaded cation exchanger, calcium ions are exchanged for potassium ions. The cation exchanger is regenerated with potassium chloride solution. The product solution contains only the valuable constituents potassium, phosphate, and nitrate; the byproduct solution from regeneration contains the unwanted calcium and chloride, which are removed.

Production. The product solution is treated in the usual way to give granular NPK fertilizers.

The process was developed in the late 1960s, and an industrial plant began operating at the end of 1971 in Fredericia, Denmark.

Conventional chloride-free NPK fertilizers based on potassium sulfate contain ammonium nitrate, ammonium phosphate, and potassium sulfate. In NPK fertilizers based on ion exchange, the potassium sulfate is replaced by potassium nitrate.

Products based on ion exchange can be made with a higher total content of nitrogen, phosphorus, and potassium nutrients because they do not contain "ballast" sulfate. A typical N-P_2O_5-K_2O grade is 17-17-17; the corresponding grade in potassium-sulfate-based processes is 15-15-15.

The presence of potassium nitrate instead of chloride or sulfate has a favorable effect on physical properties. Ammonium chloride formation, which often causes caking problems, does not occur. The presence of nitrate instead of chloride or sulfate facilitates production of hard, uniformly sized granules with good storage properties in a spherodizer.

11.6. Nitro Process with Sulfate Recycle (DSM)

Phosphate rock is acidulated with nitric acid at 65 °C (Fig. 42, c). Phosphoric acid may also be added. Calcium nitrate in the slurry is then reacted with ammonium sulfate at 55 °C (d) to form calcium sulfate dihydrate [110].

Figure 42. The DSM nitro process for production of NPK fertilizer with sulfate recycle
a) Rock bin; b) Belt weigher; c) Digestion; d) Reactor; e) Filter; f) Conversion plant (see Fig. 39)

The slurry is filtered (e) and the gypsum filter cake is fed to the ammonium sulfate recovery section where 52 – 53 % ammonium carbonate solution is used to produce a slurry of ammonium sulfate solution and solid calcium carbonate. A 40 % ammonium sulfate solution is obtained for recycle, after filtration of the calcium carbonate (Fig. 39). The mother liquor from the filter is mixed with phosphoric acid to increase the P_2O_5 water solubility of the final product. After neutralization the remaining moisture is removed by steam evaporators before the product is mixed with other nutrients and prilled or granulated.

A feature of this process is the absence of straight nitrogen fertilizer coproduct, although low N/P_2O_5 ratios are obtained only by the addition of other P_2O_5 materials (phosphoric acid, triple superphosphate, or MAP).

The use of a mixture of acids to produce nitrophosphates was developed to eliminate calcium nitrate as a final coproduct. Some of the calcium nitrate formed during acidulation of the phosphate rock with nitric acid remains in the slurry after filtration and ends up as DCP in the final product. To increase the P_2O_5 water solubility above 30 %, large amounts of phosphoric acid must be added.

11.7. Effluent Control of Nitrophosphate Process

Gaseous emissions from the nitrophosphate process are especially low in fluorine; <1 % of the fluorine in the rock evolves during digestion. The concentration of nitrous gases can be reduced by addition of urea [101]. The NO_x concentration of the stack gas is <150 ppm. Furthermore, ammonia-containing effluents can be collected and treated before recycling to the process as ammonium nitrate or gaseous ammonia.

Emissions from the dry section of the plant handling solid materials are treated in cyclone or filter systems. For granulation units, treatment similar to that described for the sulfur route and MAP production is required (Chaps. 9 and 10). The prilled product consists of even particles with a smooth surface; dust generation from a prilling process is therefore considerably lower than in a granulation plant. The dust collected in these systems is recycled to the process.

Dust emission from the prilling tower is very low in nitrophosphate production, compared to the production of straight fertilizers (e.g., urea or ammonium nitrate). Thus treatment systems are not needed for the cooling air.

12. Other Straight Phosphate Fertilizers

12.1. Phosphate Rock for Direct Application

The agronomic effect of directly applied phosphate rock is assumed to be related to the degree of carbonate substitution for phosphate within the apatite structure. Carbonate fluorapatite is less resistant against weathering and may thus release P_2O_5 into the soil [111]. These rocks are often called soft phosphate rocks.

Only sedimentary rocks are suitable for direct application. Rock from North Carolina (30.1 wt % P_2O_5) and Tunisia (28.7 wt % P_2O_5) is most reactive (86.3 and 74.6 % P, respectively, extracted by 2 % formic acid) [112], [113].

World use of rock for direct application (excluding China) in 1989 was ca. 1.2×10^6 t P_2O_5 (i.e., about 3.5 % of total phosphate use). The main users worldwide are the former Soviet Union, France, Malaysia, and Sri Lanka.

Application. Direct application of reactive rock is most useful for gradually building up

the phosphate status of an acid soil or for maintaining phosphate levels in soil that already has a high status.

Reactive rocks can be used to provide an "insurance" for crops that are not particularly responsive to phosphate (e.g., perennial grazed grassland, established tree crops, and paddy rice). Crops that have a high calcium uptake (e.g., legumes) can often extract more phosphate from rock sources. Rock is least satisfactory for small-seeded annual crops or crops grown at low soil temperature.

Phosphate rock is not readily soluble in soil and can therefore only be used to build up soil reserves. However, the slow dissolution means that phosphate ions are still being released several years after application [114]. The best chemical test of the potential dissolution rate of phosphate rock is provided by extraction with 2 % formic acid.

Dissolution is aided if the phosphate rock is "soft" or if it is finely ground and applied as a powder.

Dissolution also improves if the soil is moist and acidic (pH<5.5), but the proportion of phosphate taken up by a crop decreases with increasing soil acidity [115]. Models of dissolution rate in soil are described in [116], [117].

Production. Run-of-mine rock is ground, screened, and applied directly to soil without further treatment. The rock must be ground to a particle size of 0.15 – 0.075 mm [118]. Handling problems associated with this finely ground, dusty material can be alleviated by granulation.

The minigranulation process developed by IFDC compacts finely ground phosphate rock into spherical granules by use of a binder [119]. Binders include soluble salts, mineral acids, and organic materials. Granules made with a soluble salt binder disintegrate in soil and are almost as effective as finely ground rock.

12.2. Partially Acidulated Phosphate Rock [118]

Partially acidulated phosphate rock (PAPR) consists of a mixture of immediately available MCP and gypsum (calcium sulfate). The amount of MCP present is determined by the degree of acidulation. Typically, PAPR is produced by using 50 % of the acid required for full conversion to superphosphate.

Very little PAPR is in commercial production. The main use is in New Zealand where ca. $(75-100)\times10^3$ t of P_2O_5 are produced in PAPR form.

Application. A PAPR mixture has potential agronomic advantages because it combines the immediate effect of water-soluble MCP with the prolonged release of the rock. In a responsive situation, the water-soluble fraction is most beneficial if the fertilizer is granulated and placed near the crop roots, but such placement reduces the value of the rock component.

The agronomic value of PAPR is affected by the "softness" of the original rock as well as by soil and crop factors that influence the agronomic value of directly applied rock. This value is often surprisingly high under laboratory conditions [120].

The PAPR is most valuable in moist, acid soil with moderate phosphate status where the crop is not particularly responsive. The crop should then obtain its immediate phosphate needs from MCP, whereas the rock fraction maintains or builds up the general phosphate status over time.

Partial acidulation improves the agronomic performance of almost all rocks but probably has economic advantages over full acidulation (i.e., production of superphosphates) only in areas where crops show little or no immediate response and in soils where the rock component dissolves rapidly enough to maintain the soil at a satisfactory phosphate status.

Production. Sulfuric and phosphoric acids are most commonly used for partial acidulation. The former is generally preferred for economic reasons. Two processes have been evaluated for the production of sulfuric-acid-based PAPR [121].

The *run-of-pile (ROP) process* is simpler and may be operated in one or two stages. Ground phosphate rock, sulfuric acid, and water (if required) are fed continuously to a mixer (usually of the pugmill type). Retention time in the mixer is 30 – 60 s. Continuous operation is preferable to batch operation to avoid poor product handling as well as excessive agglomeration and caking. Other materials can be added to the

mixer to improve acidulation or provide additional nutrients.

Depending on the characteristics of the rock and the degree of acidulation, the product can be transferred directly from the mixer to storage without curing or denning. It is typically stored for two weeks before being reclaimed, crushed to pass through a 4-mm screen, and prepared for dispatch.

In the *single-step acidulation – granulation process* the feed includes recycled material (product screen undersize and some product). Depending on the rock and the operating conditions, the recycle to product ratio in the feed is ca. 2. Retention time in the granulator is usually 5 – 8 min.

The moist, plastic product leaving the granulator is fed to a rotary drum dryer. After being dried, the granules are screened in a closed circuit with a crusher to obtain a product size of 1 – 4 mm.

Table 3. Composition of basic and BOF slag fertilizers

Composition or property	Basic slag (Thomas phosphate), wt %	BOF slag (Thomas kalk), wt %
Typical values		
P_2O_5 (citric acid soluble)	13–15	4–8
$CaO + MgO$	45–50	45–55
SiO_2	8–12	ca. 12
$Fe(FeO + Fe_2O_3)$	8–12	12–18
Mn, Al, and trace elements	2–4	3–6
German regulation requirements		
Minimum citric acid soluble P_2O_5	10	3
Minimum CaO		35
<0.16 mm	>75	
<0.63 mm	>96	
<0.315 mm		>80
<1.0 mm		>97
Color	brownish gray	
Density	ca. 3.2 g/cm^3	
Bulk density	ca. 1.6 g/cm^3	
Tapped density	ca. 2.1 g/cm^3	

12.3. Basic and BOF Slag Fertilizers

The origin of basic fertilizer slag and basic oxygen furnace (BOF) slag is apatite from magmatic iron ores. The slag is separated during steel production by addition of lime. Excess lime and silica (sand) can be added to increase the fertilizer value and give porous crystals of calcium silicophosphate, $Ca_5P_2SiO_{12}$ (silicocarnotite). Slag composition varies with origin and process; BOF slag has a lower P_2O_5 content. Typical values and German fertilizer regulation requirements are given in Table 3.

Since the mid-1960s the production of phosphorus-containing fertilizer slag has declined because the steel industry requires high-quality ores with a low phosphorus content. Today, only iron ores from Kiruna (Sweden) and Lorraine (France) yield phosphorus-containing fertilizer slag. Annual EC production of basic slag is ca. 220 000 t of P_2O_5 (1.6×10^6 t of slag) and of BOF slag ca. 12 000 t of P_2O_5 (220 000 t of slag).

Application. The fertilizing effect of slag increases with its silica content. Many years ago, extra sand was sometimes added to liquid slag either during the slagging process or while the slag stream was being poured off. At present, nearly all basic slag fertilizers have a high citric acid solubility (>80 %).

Production. Basic slag is produced as a byproduct in the basic Bessemer process for melting phosphorus-containing iron ores.

In all steel-making processes based on blowing with air or oxygen, oxidation of phosphorus-containing iron in the converter produces both steel and phosphorus-containing slag. All elements that are initially reduced in the blast furnace along with the iron oxide are subsequently oxidized in the converter at high temperature. They accumulate in the slag to form calcium silicophosphate. At the end of the blowing process, liquid slag floats on the molten steel surface. This slag consists mainly of a lime – phosphate – silicate melt, as well as certain amounts of iron and manganese oxides.

Addition of phosphate rock to the converter as a replacement for lime has frequently been recommended to increase the P_2O_5 content. Such addition cannot be used if the phosphate contains fluorine because this severely reduces the solubility of the basic slag in 2 % citric acid due to apatite formation. Use of fluorine-free phosphates gives the desired increase in the citric-acid-soluble phosphate fraction of the slag [122].

In the basic Bessemer process for oxidizing carbon, phosphorus, silicon, etc., oxygen is introduced in the form of air blown through the bottom of the converter. The use of pure oxygen instead of air has led to a series of other steel production processes (→ Steel). A basic slag containing bound P_2O_5 is formed by blowing the oxygen through a lance from above (Linz – Donawitz Arbed Centre process, LDAC) or through nozzles on the floor of the converter (Oxygen Bottom Maximilianshütte process, OBM). The oxygen blast can be interrupted before complete decarburization of the melt (ca. 0.7 %) occurs; most of the "first slag" is then poured off. The "second slag", formed after final blowing of the melt, remains in the converter and is reprocessed with the next melt (two-slag process). The first slag resembles basic Bessemer slag, but has a lower iron and a higher P_2O_5 content (5 – 7 % Fe, 18 – 22 % P_2O_5). It is marketed as basic slag [123]. In the one-slag process the charge is blown until dephosphorization is complete, and mixed slag with a lower phosphate content is produced.

Separation of the Slag. The converter containing liquid slag floating on the molten steel is tilted. Slag flows into a trolley where it solidifies to a solid block, which is then taken to the slag heap where it cools. When the slag solidifies, considerable segregation occurs in the interior of the block, resulting in virtually complete separation of lime-rich phosphates, and iron and manganese oxides [124].

The LDAC and BOF slags are poured into flat beds for technical reasons. This allows rapid cooling and thus speeds up further processing.

The slag begins to solidify even at high temperature and thickens rapidly. Complete dissolution of the added sand is therefore difficult. Moreover, the melting point of silicophosphate in the slag increases with increasing silica content. Sand is therefore sometimes dried and mixed with ground coke before being added. Thorough mixing results in reaction of the coke with iron oxides in the slag.

Constitution. The shaded area in the phase diagram in Figure 43 shows the composition of commercial basic Bessemer slags, when the iron oxides and manganese oxide present are ignored. The line connecting $3\,CaO \cdot P_2O_5$ and $2\,CaO \cdot SiO_2$ clearly separates the lime-rich part of the ternary system from the rest because the melting points that occur on this line are all much higher than those of the neighboring phosphorus-rich compositions. The orthophosphate $3\,CaO \cdot P_2O_5$ and the orthosilicate $2\,CaO \cdot SiO_2$ are extremely stable and therefore dominate the crystal phases in the basic slag. The two phases have similar crystal structures, leading to formation of a solid solution series during crystallization. Calcium silicophosphates are almost 100 % soluble in 2 % citric acid and are present in concentrations of 60 – 80 wt % in normal basic slag or in slag produced by the LDAC or the OBM process [125].

Figure 43. Phase diagram for calcium silicophosphates

The crystal phase changes that occur during cooling contribute largely to the physical properties of the slag.

Size Reduction. The blocks of slag disintegrate during the course of weeks or months. The resulting particle sizes vary greatly between extremely fine powder and larger pieces. Rapid cooling in a slag bed prevents spontaneous breakdown of the slag so that further grinding is necessary.

The slag is ground in ball mills or tube mills to a fineness of at least 75 % <0.16 mm. In the mill, efficient dust removal is necessary because prolonged inhalation of basic slag phosphate dust can damage the respiratory tract owing to the presence of silicates and silicophosphates (basic slag is covered by the "2. Verordnung zur änderung der Gefahrstoffverordnung," Bundesgesetzblatt dated April 23, 1990, Part 1).

Attempts to manufacture granulated basic slag phosphate directly on a large scale have so far not been successful for economic reasons [125].

12.4. PK Mixed Fertilizers with Basic Slag

Increasing quantities of granulated mixtures of basic slag and potash salts are used as PK mixed fertilizers with $P_2O_5 : K_2O$ ratios between 1 : 1 and 1 : 3. They are usually produced by agglomerating the powdered basic slag and potassium salts in double-shaft granulators, followed by granulation by rolling in cylindrical drums and drying with hot gases. Inorganic substances are used as granulation aids [126].

The addition of fused phosphates or DCP is legally permitted to allow the P_2O_5 content of the slag to be adjusted to maintain a constant P/K ratio [127].

13. Energy Consumption [128]

Phosphate rock is the raw material for phosphate fertilizers. Approximately 5 t of ore must be mined and beneficiated to produce 1 t of commercial phosphate rock with an average phosphorus content of 14 % (32 % P_2O_5). This process requires 0.9 GJ/t or 2.9 GJ/t of P_2O_5. If the rock is calcined, the total energy requirement is doubled. Sulfuric acid is required for the production of phosphoric acid, which is an intermediate for 80 % of the phosphate fertilizers worldwide. The energy contribution for sulfuric acid varies from an export of 8 GJ/t of P_2O_5 to a requirement of 7 GJ/t of P_2O_5 depending on the raw materials.

Production of phosphoric acid (54 % P_2O_5) from sulfuric acid and uncalcined rock requires between 10.8 GJ/t of P_2O_5 (hemihydrate) and 12.9 GJ/t of P_2O_5 (dihydrate).

Processing the acid to ammonium phosphate fertilizers requires a further 1.5 – 1.75 GJ/t of P_2O_5. Processing to triple superphosphate requires a further 2.6 – 3.5 GJ/t of P_2O_5.

Complex fertilizers based on the nitrophosphate route require a minimum of 5.5 GJ/t of P_2O_5 to process the rock to complex phosphate fertilizers.

14. Effluents from Phosphate Fertilizer Production

Disposal of gypsum-containing effluents in the sea is the main environmental concern in phosphate fertilizer production. Some companies have established land disposal and eliminated all gypsum effluents.

Emissions from phosphate fertilizer production vary considerably, normally depending on the age of the plant (Table 4).

Table 4. Emission levels from phosphate fertilizer plants

Emitted substance	Modern plants	Old plants
To air		
NH_3, kg N/t N	0.01	1–10
NO_x, kg N/t N	0.3	0.5–4
F, kg F/t P	0.01	<0.12
To water		
$NH_4^+ + NO_3^-$, kg N/t N	0.01	0.6–5
PO_4^{3-}, kg P/t P	0.15	1.0–4
F, kg F/t P	0.06	0.9

Nutrient losses during fertilizer production are <1 % of the nutrients handled in old plants and <0.04 % in modern plants. Thus, the main environmental concerns associated with fertilizers are not at the production site but on the farm (→ Fertilizers, Chap. 9.2.1.).

15. Heavy Metals in Phosphate Fertilizers

Many elements that do not appear to be necessary for plant nutrition occur in the raw materials used for fertilizer production and thus in small amounts in fertilizers.

Table 5 lists the heavy metals found in phosphate rocks and compares typical contents with those found in soil. Contents vary widely with origin and type of rock [129].

In the sulfur route, 80 – 90 % of the mercury and lead and 30 – 50 % of the cadmium end up in the gypsum waste. In the other processes, almost all the trace elements end up in the phosphate fertilizer.

Table 5 also gives the input of heavy metals to a topsoil after a century's use of phosphate

Table 5. Heavy-metal content of phosphate rock and soil [129]

Element	Average content*, mg/kg P	Range, mg/kg rock	Average content, mg/kg		Input to soil after 100 years of fertilizer use, mg/kg soil**
			Rock	Soil	
Arsenic	45	1–300	7	6	0.04
Cadmium	170	0.01–120	25	0.35	0.14
Chromium	1000	0.3–460	150	70	0.83
Cobalt	13	0.5–6	2	8	0.01
Copper	200	6–80	30	30	0.17
Lead	40	3–40	6	35	0.03
Manganese	200	6–300	30	1000	0.17
Mercury	0.2	0.01–0.10	0.03	0.06	0.0017
Molybdenum	33	1–10	5	1.2	0.03
Nickel	230	1–85	35	50	0.19
Zinc	660	3–800	100	90	0.55

* 15% P in rock. ** Topsoil (20 cm soil), soil volume weight 1.2 kg/L, annual application of 20 kg P/ha for 100 years.

fertilizer. This input is small compared with the levels naturally present in the average soil, with the notable exception of cadmium.

Cadmium is highly toxic to humans but less so to plants. Concern exists that the use of phosphate fertilizers will slowly increase the cadmium content of arable land and that within about a century this might eventually result in an unacceptably high cadmium level in agricultural produce.

The average daily cadmium intake in the European diet is 20 µg; WHO recommends a maximum daily limit of 70 µg.

Table 6. Phosphorus and cadmium content of phosphate rocks [129]

Type of rock	Phosphorus content, wt%	Cadmium content	
		mg/kg rock	mg/kg P
Magmatic origin			
Kola, Soviet Union	17.2	0.15	0.9
Palfos, Republic of South Africa	17.2	0.15	0.9
Sedimentary origin			
Bou Craa, Morocco	15.9	35	220
Togo	15.7	55	350
Youssofia, Morocco	14.6	40	274
Jordan	14.6	5	34
Texas Gulf, USA	14.4	40	278
Florida, USA	14.4	8	56
Negev, Israel	14.2	20	140
Khouribga, Morocco	14.2	16	113
Khneifiss, Syria	13.9	6	43
Gafsa, Tunisia	13.2	50	380

Fertilizers can contain cadmium if sedimentary rock phosphate is used as a raw material. Table 6 shows typical values for cadmium content in some important rock phosphates.

No commercial process is currently available for removing cadmium from phosphate fertilizers. Several companies are, however, carrying out research into the development of cadmium removal processes. The most promising processes involve separating cadmium from phosphoric acid for the sulfur route and from the mother liquor for the nitro route.

16. Safety in Storage, Handling, and Transport

Phosphate fertilizers without free phosphoric acid are regarded as nontoxic, with no dangerous properties.

Phosphate substances that are handled as fertilizers do not present a specific health risk nor do they have undesirable chemical effects. Their transport is therefore not covered by dangerous goods regulations.

Phosphatic raw materials and many fertilizer products are transported in bulk. The physical stability of the contents of the ship hold in marine transport is a risk factor during loading and voyages in rough seas. The International Maritime Organization (IMO) takes these risks into consideration and specifies values for cohesiveness and angle of repose [130].

Phosphate compounds are present in compound NP or NPK fertilizers, often with nitrates as the nitrogen source. Nitrates have some sensitivity to heat. Different grades of these fertilizers

are listed in the UN's "Recommendations on the Transport of Dangerous Goods" and in the specific codes for all transport modes.

Self-sustaining decomposition (SSD) is linked predominantly to NPK grades but may also be observed in NK grades. The thermal stability of fertilizer products is tested in a standardized procedure (the trough test) [131]. If the product exhibits SSD after the heat source is removed, the product is assigned to Class 9. If the velocity of SSD exceeds 25 cm/h, bulk transport is prohibited. For NPK grades SSD may be favored by a low water solubility of phosphorus in KCl-based, nitrate-containing commodities.

1. Monophosphoric Acid

Klaus Schrödter and Gerhard Bettermann

Phosphoric acid was first prepared in 1694 by BOYLE from P_4O_{10} soon after the discovery of elemental phosphorus.

1.1. Properties

Physical Properties. Pure, anhydrous phosphoric acid , H_3PO_4, M_r 98, *mp* 42.35 °C [1], ϱ 1.88 g/cm^3, is a colorless, crystalline compound, that is readily soluble in water.

A hemihydrate of phosphoric acid, $H_3PO_4 \cdot ½ H_2O$, *mp* 29.25 °C, is also known.

Figure 1 shows the H_3PO_4 – H_2O phase diagram [2].

Figure 1. H_3PO_4–H_2O phase diagram

Phosphoric acid is infinitely miscible with water. It is commercially available in three standard concentrations:

75 % H_3PO_4 with 54.3 % P_2O_5, *mp* –20 °C
80 % H_3PO_4 with 58.0 % P_2O_5, *mp* 0 °C
85 % H_3PO_4 with 61.6 % P_2O_5, *mp* +21 °C

The 85 % acid (ϱ 1.687 g/cm^3) has syrupy consistency. It tends to supercool, especially when transferred to glass bottles. It is usually stored in heated containers in order to avoid crystallization. The anhydrous acid can be obtained from the 85 % acid by evaporation in vacuum at 80 °C.

Figures 2 and 3 show plots of the density and viscosity of phosphoric acid against concentration and temperature. The density is practically constant in the temperature range 25 – 100 °C. As shown in Figure 4, the same is true of the specific heat.

Figure 2. Density of phosphoric acid as a function of concentration and temperature

Figure 3. Kinematic viscosity of phosphoric acid as a function of concentration and temperature

Figure 4. Specific heat of phosphoric acid as a function of concentration and temperature

The boiling point of phosphoric acid as a function of concentration and the composition of the corresponding vapor phases are shown in Figure 5 [3]. Only traces of P_4O_{10} are present in the gas phase at temperatures up to 300 °C. P_4O_{10} appears in the vapor phase only above this temperature after condensation of phosphoric acid to form polyphosphoric acids.

Figure 5. Liquid – vapor equilibrium diagram of the P_4O_{10} – H_2O system

Chemical Properties. Monophosphoric acid is tribasic. The dissociation constants are $K_1 = 7.1\times10^{-3}$, $K_2 = 6.3\times10^{-8}$, and $K_3 = 4.7\times 10^{-13}$.

Accordingly, primary, secondary, and tertiary salts are formed with bases. Aqueous solutions of dihydrogenphosphates are weakly acidic, while those of hydrogenphosphates and tertiary phosphates are weakly or strongly alkaline, respectively. As shown in Figure 6, mixtures of dihydrogenphosphates and hydrogenphosphates act as buffers, e.g., in the range pH 6 to 8.

Figure 6. Ion concentration of a phosphoric acid (phosphate) solution as a function of pH

1.2. Production

Two methods are used for the industrial production of phosphoric acid. The wet digestion of phosphate rock with mineral acids is the most important process in terms of volume. Digestion is usually carried out with sulfuric acid, but nitric acid [4] or hydrochloric acid [5] are also used to a lesser extent. The acid obtained in this process is called wet phosphoric acid.

The second process for the production of phosphoric acid starts with elemental phosphorus, which is obtained from crude phosphate, coke, and silica in an electric resistance furnace (⟶ Phosphorus), and subsequently oxidized to P_4O_{10}. The acid obtained by hydration of the oxide is generally termed thermal phosphoric acid.

1.2.1. *Thermal Processes*

The production of phosphoric acid from elemental phosphorus is carried out in two stages: combustion with excess air to give P_4O_{10} and hydration of P_4O_{10} to form H_3PO_4:

$$P_4 + 5\,O_2 \rightarrow P_4O_{10}\ \Delta H = -3053\,\mathrm{kJ/mol} \quad (1)$$

$$P_4O_{10} + 6\,H_2O \rightarrow 4\,H_3PO_4\ \Delta H = -377\,\mathrm{kJ/mol} \quad (2)$$

The IG and Tennessee Valley Authority (TVA) processes for the production of phosphoric acid are distinguished by the method of absorption and hydration of P_4O_{10}. The Hoechst process differs from these in that it utilizes the heat of phosphorus combustion for steam generation.

IG Process [6]. In the IG process (Fig. 7), phosphorus combustion and P_4O_{10} absorption are carried out in a single stage in a common tower. The tower walls are slightly conically inclined so that the recycled acid, overflowing inside from a cup located at the tower head, can completely cover the wall with an acid layer. This protects the wall from the phosphorus flame that descends from the tower head and reaches a temperature > 2000 °C. The recycling phosphoric acid dissolves the phosphorus pentoxide formed and dissipates the heat from the reaction zone. It is collected below the acid tower and recycled to the tower cup after passing through the heat exchanger.

Figure 7. Production of thermal phosphoric acid (IG process)

a) Nozzle; b) Combustion tower; c) Overflow cup; d) Heat exchanger; e) and f) Venturi scrubbers; g) Receiver for wash acid; h) Off-gas fan; i) Separator

Phosphoric acid overflows from the tower cup at ca. 60 °C and is heated on the way along the tower walls to up to 85 °C. About 80 % of the heat generated is dissipated by the cooling water, 17 % by off-gas and water evaporation, and 3 % by the sensible heat of the acid.

The phosphorus is sprayed into the tower from a binary nozzle by pressurized air or steam at up to 1.5 MPa. It is ejected from the nozzle at such a high speed that the phosphorus flame is kept away from the head and cannot damage it. A slight underpressure is maintained in the tower, generated by a fan which draws the combustion air from an annular aperture around the nozzle at the tower head. The off-gas is discharged in the wash stage. Here, P_4O_{10} that is entrained in the off-gas in the form of aerosol or acid droplets is separated. It accounts for ca. 30 % of the total conversion. The wash acid is added to the tower acid. Venturi systems, wash towers operated with or without packing, or demister elements packed with glass fibers are used as separators [7].

All parts of the equipment which come into contact with P_4O_{10}-containing off-gases are made of rubber- coated steel, stainless steel, or plastic. A stainless steel with very low carbon content, stable against concentrated phosphoric acid at up to 100 °C, has prevailed as construction material for the acid tower.

In addition to the phosphoric acid flowing down on the tower walls, phosphoric acid is sprayed into the tower through nozzles in the lower tower half below the phosphorus flame and perpendicular to the off-gas flow. This decreases the off-gas temperature to ca. 100 °C.

The orthophosphoric acid obtained is virtually free of lower phosphorus oxides and its H_3PO_3 content is 0.1 %.

Thermal phosphoric acid contains only traces of impurities due to the use of pure phosphorus for combustion. Only arsenic, a natural companion of elemental phosphorus which is contained in the acid at a concentration of 5 –30 ppm, need be removed in a further purification step. This is accomplished by precipitation of arsenic sulfide with hydrogen sulfide followed by filtration. The hydrogen sulfide is generated by injecting Na_2S solution into the phosphoric acid. This is done either in a precipitation tower with subsequent filtration after addition of activated charcoal and kieselgel [8], or more directly and simply in a centrifugal pump which immediately conveys the acid to the filter [9].

TVA Process [10]. In the Tennessee Valley Authority (TVA) process phosphorus combustion and P_4O_{10} absorption are carried out separately (Fig. 8).

Figure 8. Production of thermal phosphoric acid (TVA process)

a) Storage tank; b) Combustion chamber; c) Absorption tower; d) Cooled receiver; e) Venturi scrubbers; f) Dilute acid tank; g) Separator

The vertical, cylindrical, stainless steel phosphorus combustion chamber is externally cooled. The phosphorus burner is installed laterally and is directed downwards toward the bottom of the combustion chamber at an angle of ca. 40°.

The gas discharge and the connection to the absorption tower are located at the top of the combustion chamber. A layer of polyphosphoric acid is formed from generated P_4O_{10} and atmospheric moisture, which protects the inner walls against corrosion. The polyphosphoric acid contains ca. 92 % P_2O_5, and its vaporization point is 867 °C. Phosphorus and air are introduced in a manner similar to the IG process.

The stainless steel cylindrical absorption tower with a conical head is also externally cooled. The inner tower walls are sprayed with dilute phosphoric acid from the off-gas purification stage and with recycled, concentrated phosphoric acid such that an unbroken acid film is formed. The phosphoric acid so produced contains 54 – 83 % P_2O_5.

A significant part of the P_4O_{10} product is entrained in the gas flow from the absorption tower. Thus, depending on whether the product is orthophosphoric acid (54 % P_4O_{10}) or superphosphoric acid (83 % P_4O_{10}), 40 – 70 % of the acid produced accumulates in the gas purification stage. Venturi scrubbers, wash towers, and demisters with webs made of special steel are used for flue-gas purification.

Hoechst Process [11]. The heat generated by combustion of phosphorus is unused and is dissipated by cooling in the IG and TVA processes. In the Hoechst process (Fig. 9), operated industrially since 1989, this energy is used for steam generation. Phosphorus combustion and P_2O_5 hydration are performed separately.

Figure 9. Schematic of the Hoechst process

a) Storage tank; b) Air dryer; c) Burner; d) Combustion chamber; e) Separator; f) Superheater

Liquid phosphorus and dried air are injected into the bottom of a vertical stainless steel combustion chamber and are combusted to give P_4O_{10}. The walls of the combustion chamber are made of pipe coils through which deionized water is pumped. The steam – condensate mixture formed in the coils by dissipation of the heat of combustion is kept at a pressure of 15 – 18 MPa. The mixture is separated into gas and liquid in a separator. The remaining condensate is returned to the water storage tank, and the evaporated portion is replenished by addition of deionized water. The high-pressure steam is transferred from the separator to the combustion chamber, where the steam temperature is increased to 400 – 500 °C at 15 – 18 MPa in a superheater. The pressure is then released, and the steam is saturated with water and used as a heat-transfer medium. The heat dissipation in the phosphorus combustion is controlled so that the temperature of the P_4O_{10}-containing off-gas is high enough to avoid separation of P_4O_{10} on the way to the absorption tower, where hydration of P_4O_{10} is carried out. An acid film is formed on the tower walls by concentrated recycled acid, similar to the IG process.

1.2.2. *Wet Processes*

The digestion of phosphate rock with sulfuric acid has been known since the mid-1880s. However, intensive research and development in this area started only after World War II, due to increased use of mineral fertilizers.

The digestion of fluorapatite with sulfuric acid proceeds according to Equation 3:

$$Ca_5(PO_4)_3F + 5\,H_2SO_4 + 5xH_2O \rightarrow 5\,CaSO_4 \cdot xH_2O + 3\,H_3PO_4 + HF \qquad (3)$$

$$x = 0, 1/2, 2$$

However, concurrent side reactions occur with other, secondary components of the crude phosphate. Their reaction products are then largely dissolved in the wet phosphoric acid. The typical composition of crude wet phosphoric acid (in wt %) is as follows:

P_2O_5	30.0
SO_3	2.1
F	2.17
Si (mainly as SiF_6^{2-})	0.41
Ca	0.45
Mg	0.13
Fe	0.08
Al	0.04
Cr	0.022
Zn	0.019
V	0.013
Ni	0.0034
Cu	0.0027
Mn	0.0009
As	0.0007
Pb	0.0002

Calcium sulfate can precipitate in three different modifications, depending on the temperature and the phosphoric acid concentration (Fig. 10). The designation of the various wet processes is derived from the modification formed in the digestion stage. Thus, dihydrate (DH) and hemihydrate (HH) processes are distinguished. In other processes, two crystalline forms are formed sequentially and separated by recrystallization (HH/DH or DH/HH processes).

Figure 10. Stability range of calcium sulfate and its hydrates in phosphoric acid

So far, the development of an anhydrite process has failed because the high reaction temperature of 120 – 130 °C required for anhydrite formation causes insurmountable corrosion problems.

Two basic operations are common to all wet phosphoric acid processes: digestion in a reactor and removal of $CaSO_4$ by filtration.

Reactors. Originally digestion was carried out in several large stirred tanks arranged in series, with recirculation of the digestion slurry by pumps. The introduction of single tanks brought an essential simplification as well as an improvement of the circulation for compensation of temperature and concentration fluctuations, and thus for optimization of the crystallization conditions [12], [13]. Round models (see Fig. 11) as well as rectangular ones were constructed. In the round single tank, the reaction components are slowly moved in a circle in the outer, annular space with vigorous, local agitation. Part of the digestion slurry overflows into the central space and flows to filtration. In medium-sized facilities (200 – 400 t/d P_2O_5), air is blown onto the surface for dissipation of the heat of reaction (2 GJ/t P_2O_5 in a DH process). In larger plants, the heat is dissipated by vacuum evaporation of water from a recycled partial stream of the slurry in a flash cooler [14], [15].

Figure 11. Single tank round model

a) Outer annular section; b) Agitators; c) Partition; d) Cooling air nozzles; e) Center section; f) Outer passage; g) Passage to the center cylinder; h) Carbon bricks; i) Overflow channel

Filters. About 4 – 6 t of $CaSO_4$ per tonne of P_2O_5 produced must be filtered from the wet phosphoric acid. After initially using box band filters [16], producers switched to the use of plane and tilt-cell filters (Prayon, Bird, Eimco, UCEGO [13], [15], [17], [18]). The effective filter area can approach up to 200 m^2. Later, band filters with larger outputs and filter areas exceeding 100 m^2 became available. In the filtration, the wet phosphoric acid is drawn off from the solids in a partial vacuum. Adhering acid is washed off the solids in two or three stages in countercurrent. The wash acid is discharged separately and recycled to the reactor. The discharge of the filter cake is carried out by tilting the filter pans, by means of a screw conveyor, or by stripping from the band.

Due to technical progress in reactor and filter construction, production units for wet phosphoric acid now have capacities up to 1000 t/d of P_2O_5.

Dihydrate Process. The dihydrate process is the classical method for the production of wet phosphoric acid (Fig. 12). Prior to digestion, the phosphate rock must usually be ground to a fineness of 75 % < 150 µm. Phosphate rock and concentrated sulfuric acid are charged spatially separated. In this way, the concentration of sulfuric acid is lowered so that the digestion occurring at the phosphate rock charging point is not hindered by formation of a gypsum layer on the ore particles. In addition, the formation of too many gypsum seed crystals due to supersaturation of Ca^{2+} and SO_4^{2-} ions is avoided. The calcium sulfate is present as the dihydrate at a reaction temperature of 70 – 80 °C and a phosphoric acid concentration of 28 – 31 %. Usually, the filtered acid is further concentrated (see Section Concentration of Wet Phosphoric Acid).

Figure 12. Flow diagram for the DH process

a) Metering device; b) Scrubber; c) Filters; d) Single tank; e) Thickener; f) Discharge tank

Advantages of the dihydrate process are the low reaction temperature and, therefore, fewer corrosion problems; its applicability to most grades of phosphate rock; and its suitability for large-volume production. Some disadvantages are the production of a comparatively dilute phosphoric acid which must subsequently be concentrated; the need to grind the phosphate rock; and the relatively high P_2O_5 losses of 4 –6 % in the gypsum.

Hemihydrate Process. Rising energy costs initiated the development of processes that allow the production of phosphoric acid with 40 – 50 % P_2O_5, without using additional concentration steps, for direct use in fertilizer production. These processes must be carried out at higher temperature in the stability range of calcium sulfate hemihydrate (see Fig. 10). Thus, single-stage (HH) and two-stage (HH/DH, DH/HH) processes were developed in which the hemihydrate is formed as end or intermediate product.

The first commercial HH/DH process was introduced in Japan. The major interest in this process was the production of pure gypsum that could be used for cement production since there are no natural gypsum deposits in this region.

There are currently 60 hemihydrate plants operating worldwide; more than half of them use a HH/DH process. The single-stage HH process has seldom been used because of the unfavorable process yield.

The various processes and some typical features are as follows:

1. *HH Process [19]*

   Features:
   - Single filtration stage
   - Impure $CaSO_4 \cdot 1/2\ H_2O$
   - Yield, 90 – 94 %
   - Phosphoric acid, 40 – 48 % P_2O_5
2. *HH/DH Process [20]*

   a. Without intermediate separation of the hemihydrate
      Features:
      - Single filtration stage
      - Pure $CaSO_4 \cdot 2\ H_2O$
      - Phosphoric acid, 30 – 32 %P_2O_5

   b. With intermediate separation
      Features:
      - Two filtration stages
      - Very pure gypsum
      - Yield, 98.5 %
      - Phosphoric acid, 40 – 52 % P_2O_5

Figure 13 shows the flow sheet for the Fison process as an example of a HH/DH process with intermediate separation of the hemihydrate [14]. In this two-stage processes, the higher digestion temperature of 85 – 110 °C increases the reaction rate and allows the use of unground phosphate rock.

Figure 13. Flow diagram for the HH/DH process

a) Metering device; b) Flash cooler; c) Gas scrubbing; d) Filters; e) Premixer; f) Digester; g) Hydration tank

Depending on the process, the conversion of the hemihydrate is carried out under different conditions. In the Nissan process, which dispenses with the intermediate separation of hemihydrate, the dihydrate is crystallized after cooling of the digestion slurry from 85 – 90 °C to 55 –65 °C [20]. In the Fison process the hemihydrate is recrystallized after filtration from a washing acid (a mixture of sulfuric and phosphoric acid: 4 – 8 % SO_3, 10 – 20 % P_2O_5) slurry.

3) DH/HH Process [14], [21]

Features:

Repeated filtration with intermediate conversion
Very pure $CaSO_4 \cdot 1/2\ H_2O$
Yield, 96 – 98 %
Phosphoric acid, 32 – 36 % P_2O_5

This process is only of interest where very high purity hemihydrate is required, for example, in plaster.

1.2.3. *Concentration of Wet Phosphoric Acid*

Most of the wet phosphoric acid produced worldwide is made by the dihydrate process. For further processing to fertilizers, the major application (⟶ Phosphate Fertilizers), the concentration of the phosphoric acid must be increased from 28 – 30 % P_2O_5 to 40 – 55 % or even 70 % P_2O_5 (superphosphoric acid). Submerged combustion burners and vacuum circulation evaporators are customary concentration devices. In the older submerged burner process, hot combustion gases from an oil burner are blown through a dip tube or directly into phosphoric acid [22]. At an acid temperature of 350 °C, the off-gases entrain high proportions of phosphoric acid as aerosols as well as volatile fluorine compounds. Purification of these off-gas streams is expensive.

Today, submerged combustion burners are still in use only in older plants. Currently, vacuum evaporation with forced circulation is the concentration method generally used (Fig. 14). Depending on the amount of water to be evaporated, one or more evaporators are used in parallel or in series. Multistage evaporators arranged in tiers of usually three stages have the advantage of lower energy costs. The energy savings result from effective heat utilization. The vapors of an evaporator stage operated at a higher temperature are used for heating another operated at a lower temperature [23]. In the concentration of phosphoric acid from 30 to 50 % P_2O_5, the steam requirements can be reduced from 1.25 t to 0.7 t per tonne of evaporated water. Rubber-proofed steel is the predominant material of construction for containers, piping, and pumps at operating temperatures below 120 °C. At higher temperatures, e.g., in the production of superphosphoric acid at up to 200 °C, alloys such as Hastelloy G 3 or Sanicro 28 are used. The heat exchanger tubes are usually made of graphite or nickel alloys.

Figure 14. Recycling evaporator for concentration of wet phosphoric acid

a) Recycle evaporator; b) Circulation pump; c) Heat exchanger; d) Condenser; e) Product takeoff; f) Pump

Apart from water vapor, a mixture of SiF_4 and HF is generated during the concentration of wet phosphoric acid. About 50 – 60 % of the fluorine content of wet phosphoric acid is volatilized on concentration from 30 to 55 % P_2O_5. In order to comply with the fluorine emission limits of the plant or to obtain a salable coproduct, concentration units are equipped with facilities for the production of H_2SiF_6. Thus, 90 – 95 % of the generated fluorine can be converted to a 15 – 25 % H_2SiF_6 solution [24].

1.2.4. *Purification of Wet Phosphoric Acid*

Wet phosphoric acid produced by wet digestion contains variable amounts of inorganic impurities, depending on the origin of the phosphate rock.

Depending on the further application, these impurities must be partially or completely removed from crude phosphoric acid. Precipitation and extraction processes are used.

Precipitation Processes. The separation of arsenic and, to an increasing extent, of cadmium is required for the use of wet phosphoric acid in fertilizer production. For separation of arsenic, a Na_2S solution is added to the crude acid, and the precipitated arsenic sulfide is removed by filtration.

The separation of cadmium by means of a complexing agent such as alkyldithiophosphoric acid alkyl ester [25] can also be classified as a precipitation reaction because the precipitated cadmium complex is separated in solid form either directly or after addition of a filter aid or absorbent. Such a process is operated on a commercial scale by Tessenderlo Chemie in Belgium.

Further purification of wet phosphoric acid by precipitation of cationic impurities, especially Fe, Al, Mg, and Ca, is possible by neutralizing the acid with caustic soda. The precipitated metal phosphates are filtered under pressure from the resulting sodium phosphate solution, which contains 18 – 20 % P_2O_5. In order to decrease P_2O_5 losses in the filter cake from > 10 % to < 5 %, [26] the filter cake is worked up with more caustic soda to give a trisodium phosphate solution and precipitatable metal hydroxides. Since the phosphoric acid in this neutralization process is converted to a phosphate salt solution, its uses are limited. For instance, wet phosphoric acid is used for the production of detergent phosphates (pentasodium triphosphate, see Section Pentasodium Triphosphate) via this route in Western Europe.

Extraction processes are the predominant methods for the purification of wet phosphoric acid. Processes are operated for the separation of single components as well as of practically all impurities in wet phosphoric acid. However, this complete purification includes measures (e.g., acid discoloration and removal of traces of arsenic and fluorine) which supplement the extraction process. The quality of such purified phosphoric acid equals that of thermally produced acid.

In 1990, production capacities for extractively purified P_2O_5 amounted to 740 000 t/a worldwide, including 300 000 t/a in Western Europe.

The basic concept for extractive purification of wet phosphoric acid is the same in all processes. Figure 15 shows a schematic of the purification steps. Crude wet phosphoric acid containing 40 – 50 % P_2O_5 is prepurified in order to largely separate, if necessary, arsenic, sulfate, and organic components by precipitation or adsorption. In the subsequent extraction process, prepurified acid is contacted with solvent countercurrently in several stages. Together with small amounts of impurities, the phosphoric acid is transferred to the organic phase, while most of the impurities remain in the aqueous phase. If a high yield of P_2O_5 (95 – 98 %) is desired, sulfuric acid is added during the extraction so that the cationic impurities remain in the aqueous phase as sulfates. In addition, so-called splitting processes are customary. In these, only 50 – 70 % of the phosphoric acid are extracted in simple plant. Phosphoric acid contained in the aqueous phase, together with the impurities, is treated further in fertilizer production.

Figure 15. Schematic of extractive purification of wet phosphoric acid

The crude extract containing the phosphoric acid is washed countercurrently with small amounts of water, phosphoric acid, or phosphate salt solutions. Depending on the wash liquid, anionic components such as SO_4^{2-} or F^- are also removed with the metal cations. The wash extract—phosphoric acid enriched in impurities—is recycled to the extraction stage. The phosphoric acid product is obtained from the purified extract by addition of water or by distillation of solvent. If further processing of the acid to commercial phosphates is intended, a phosphate salt solution can be obtained directly by addition of alkalies to the extract. The recovered solvent is recycled to the extraction stage. Usually, a partial stream is purified, for example, by distillation.

Generally, stripping for complete solvent separation and concentration of the phosphoric acid to 50 – 70 % P_2O_5 are among the posttreatment steps. In these operations, the fluoride content of the acid is also further decreased. Pressure stripping of the acid with steam to decrease the fluoride content to <10 ppm and oxidative degradation of organic

trace impurities are used for the production of food-grade phosphoric acid.

The choice of solvent is an important feature of the extraction processes. With solvents that are infinitely miscible with water, such as isopropanol [27], extraction may be complete in one or two stages. Alkali-metal or ammonium ions are added for better development of the organic and aqueous phases. Phosphoric acid is recovered from the extract by solvent distillation.

Frequently, alcohols that are partially miscible with water, such as butanol [7] or amyl alcohol [28], [29], are used. Six- to ten-stage mixer –settler units are used to attain essentially quantitative phosphoric acid extraction.

The IMI process, developed for the extraction of phosphoric acid from phosphate rock digested with hydrochloric acid, is a special case [28]: $CaCl_2$ is added as extraction aid to increase the equilibrium concentration of phosphoric acid in the alcoholic phase.

Methyl isobutyl ketone (MIBK) [30], tributyl phosphate [31], diisopropyl ether [7], or mixtures of the latter two [32] are immiscible with water. Usually, the processes based on these solvents are splitting processes without quantitative P_2O_5 extraction. The use of diisopropyl ether for extraction and reextraction is based on the temperature dependent solubility of phosphoric acid in this solvent. Extraction is carried out at 0 – 5 °C, and the acid is reseparated after addition of a small amount of water at 30 °C.

Extraction of Single Components. The first commercial processes for the separation of single components involved the production of uranium, which can be present in wet phosphoric acid at concentrations of up to 200 ppm. Large industrial plants were first operated in the 1950s with alkyl diphosphate esters [33], and in the 1970s improved processes with octyl phenyl phosphate esters, octyl diphosphate esters [34], or mixtures of di-2-ethylhexyl phosphate and tri-*n*-octyl phosphine oxide [35], [36] were introduced. However, these extraction plants were closed after several years of operation, mainly because of declining uranium prices. Only in Belgium is uranium still produced extractively from wet phosphoric acid by Prayon [37].

A process developed for the removal of cadmium involves prepurification of the acid to separate solids and subsequent extraction of cadmium into an organic phase [38]. Alkylamines are used as extractive agents in the presence of halide ions (Cl^-, I^-, Br^-). In the reextraction stage, cadmium is transferred back to the aqueous phase. Cadmium is precipitated and separated from this solution as the sulfide.

1.3. Uses and Economic Aspects

After sulfuric acid, phosphoric acid is the most important mineral acid in terms of volume and value. This is mainly due to the enormous demand for wet phosphoric acid for further processing to fertilizers. As shown in Figure 16 for the United States, the world's largest producer and consumer of wet phosphoric acid, its share of the total phosphoric acid production amounts to more than 90 %. Besides the fertilizers area, industrial phosphates (see Chap. Phosphates) and feedstuff are other areas of application of wet phosphoric acid.

Figure 16. Phosphoric acid production in the United States

About 80 – 90 % of the thermal phosphoric acid produced is used for the production of industrial phosphates, especially the sodium, potassium, calcium, and ammonium salts. Pentasodium triphosphate is always the largest single product, although purified wet phosphoric acid is being used increasingly for its production. Thermal acid is used in metal surface treatment (⟶ Metals, Surface Treatment – Phosphating) and, in food-grade quality, for the acidulation of beverages.

After decades of strong growth, a decrease of worldwide phosphoric acid production occurred in the 1980s (see Fig. 16). Ecological problems related to rising phosphate consumption are an essential cause of this development. Among these are the impairment of subsoil water by phosphate fertilizers and the eutrophication of surface waters by phosphates from fertilizers and detergents. These ecological pressures have already resulted in extensive replacement of phosphate-containing detergents and a decrease in the use of mineral fertilizers in agriculture.

1.4. Environmental Aspects

Phosphoric acid is now mainly produced (ca. 95 %) by the wet process. Because of the high energy consumption, only ca. 5 % is produced by the thermal process. An overview of the worldwide capacity in 1989 (40.6×10^6 t P_2O_5) is given in [39]. Gypsum and fluoride are the main byproducts of the wet process; phosphorus slag is a byproduct of phosphorus production by the electric furnace process.

Phosphogypsum. A quantity of 4.5 – 5.5 t impure calcium sulfate is obtained as byproduct during the production of 1 t P_2O_5 by the wet process. In 1988, 27.7×10^6 t P_2O_5 were produced and hence ca. 140×10^6 t gypsum. Disposal of these large amounts of gypsum is causing considerable problems, especially from an environmental and ecological viewpoint [40]. The gypsum contains production- and source-specific constituents (Table 1) [41]. Three possibilities for the disposal of phosphogypsum exist:

1. Dumping at sea (currently 10 %)
2. Dumping on land (ca. 88 %)
3. Use as a raw material

Table 1. Typical phosphogypsum analyses (%)

	Production process		
	Dihydrate	Hemihydrate	Hemi-/ dihydrate
CaO	32.50	36.9	32.20
SO_3	44.00	50.3	46.50
P_2O_5	0.65	1.5	0.25
F	1.20	0.8	0.50
SiO_2	0.50	0.7	0.40
Fe_2O_3	0.10	0.1	0.05
Al_2O_3	0.10	0.3	0.30
MgO	0.10		
H_2O	19.00	9.0	20.00
Process yield, t/t P_2O_5	4.9	4.3	4.9

The disposal of gypsum from production facilities near the sea is usually by outflow into the sea. Three aspects for the evaluation of the ecological consequences must be considered: (1) the large amounts of gypsum involved, (2) traces of heavy metals in the gypsum, and (3) changes in the pH of the water due to residual phosphoric and hydrofluoric acids.

The solubility of calcium sulfate in water is 2.4 g/L; in seawater it is ca. 3.5 g/L [42]. Seawater naturally contains 1.6 g/L calcium sulfate, so that, given sufficient tidal and natural movement of the water, a rapid dissolution of the gypsum is observed. SiO_2, Al_2O_3, and organic constituents remain undissolved.

The amount of heavy metals added to seawater due to phosphogypsum is relatively small in comparison to the existing levels; see Tables 2 and 3 [43], [44]. Hence, there is no enrichment of heavy metals in seawater due to this disposal method. The enrichment of the highly toxic heavy metal cadmium in the environment as a result of industrial emission is, however, viewed critically. As the result of a study [45], cadmium will be subject to increasing strict emission limits, for example, in the Netherlands [46]. The

amount of cadmium in phosphogypsum discharged into seawater in the EC in 1979 was 62 t [47].

Table 2. Trace elements in phosphate rock from Morocco and Florida and percentages thereof in phosphogypsum

Element	Morocco, ppm	Florida, ppm	Percentage in phosphogypsum
Cadmium	17	10	15 – 25
Chromium	150	≤ 90	5 – 10
Copper	28	5 – 20	4 – 8
Manganese	10	min. 100	10 – 15
Nickel	16	25 – 75	25 – 50
Uranium	120	200	15 – 20
Zinc	200	10	4 – 8

Table 3. Trace elements in seawater

Element	Concentration, kg/km^3
Chromium	48
Cadmium	120
Copper	3 360
Manganese	2 160
Nickel	2 160
Uranium	3 360
Zinc	11 280

The pH of a 10 % phosphogypsum suspension in water is 3.3. Seawater is buffered by hydrogencarbonate ions and has a pH of 7.9. Therefore, the introduction of even large amounts of slurry cannot cause the pH to drop below the critical level of 5.5 [48]. However, particular attention must be paid to the effects of dumping gypsum in the sea. Permanent surveillance of the effects of the dumping (especially with regard to accumulation) on marine flora and fauna must be carried out.

The dumping of phosphogypsum proceeds in two ways:

1. The gypsum is slurried with water and then pumped to settling vessels. The used water is generally recycled [49]. This disposal method is used especially in the United States. Problems can arise due to the difficulty of evaluating the emission of fluoride and of seepage water containing phosphate and other constituents [50]. Here, too, supervision of the ecological effects should be considered [51]. In Sweden an artificial island has been developed for the dumping of gypsum [52].
2. The dried gypsum (residual water content 20 % min.) is stored in a dump. Another possibility is the filling of empty brown coal mines with protection of the groundwater by confining the dried gypsum with polyethylene sheets [53].

For the disposal of dried phosphate sludge, special isolated disposal sections and treatment of seepage water should be undertaken to avoid environmental risks.

Due to the large amounts of phosphogypsum, the sensitivity with regard to environmental problems, and the scarcity of dumping areas, the following attempts have been made to use it as a raw material [54]:

1. Use as building material (e.g., plasterboard)
2. Cement additive
3. Use in agriculture
4. Use as a filler in the paper industry
5. Recycling to sulfuric acid and cement

The use of large amounts of phosphogypsum as raw material is generally only of economic interest in countries that do not have any natural source of gypsum. Examples are Japan and South Korea, where ca. 3×10^6 t of phosphogypsum is used, mainly in the cement industry. Otherwise only small amounts are utilized. Reasons include the impurities, the water content, the transport costs, the low price of high-purity natural gypsum, and the increased accumulation of gypsum from flue gas desulfurization [55].

Fluoride. Phosphate ore contains ca. 3.6 – 4.1 % fluoride that—depending on the process—is distributed in various amounts among the acid, in the phosphogypsum, the reactor off-gas, and the off-gases from cooling or concentration of the acid (Table 4) [56].

Table 4. Distribution of fluoride in the production of wet phosphoric acid

	Dihydrate process, %	Hemihydrate process, %
Acid	15	12
Phosphogypsum	45	50
Reactor off-gas	5	8
Flash cooler vapor		30
Concentration vapor	35	

Because of its damaging effects on the environment [57] fluoride from off-gases is either precipitated in a basic wash as CaF_2 or in an acid wash as fluorosilicate [58]. Depending on the demand the CaF_2 or fluorosilicate is either utilized or dumped. In Germany the maximum emission values for the off-gas [59] are 50 mg/m^3 for solid particles and 5 mg/m^3 for gaseous fluorine compounds.

Phosphorus Furnace Slag. Eight tonnes of slag are obtained during the production of 1 t of phosphorus by the furnace process. The slag, which consists mainly of calcium silicate, is obtained as lumps or granules.

Typical percentage slag composition is as follows:

P_2O_5	1.0
CaO	48.4
SiO_2	42.5
F	3.3
Al_2O_3	2.5
Fe_2O_3	0.2
MgO	0.6

Na_2O	0.9
K_2O	0.5

Uses of the phosphorus furnace slag are in waste-disposal technology, in road building, and as a filler and insulating material [60].

2. Condensed Phosphoric Acids

Gerhard Bettermann

During concentration of aqueous orthophosphoric acid, formation of pyrophosphoric acid can already be detected chromatographically at an orthophosphoric acid concentration of 95 %, corresponding to 68.8 % P_4O_{10}. In liquid, anhydrous orthophosphoric acid, 12.7 % is present as pyrophosphoric acid, which however, reverts to orthophosphoric acid upon crystallization [61]. Upon further concentration, a mixture of straight- chain polyphosphoric acids, $H_{n+2}P_nO_{3n+1}$, is formed initially; eventually, it is converted to a mixture of polymetaphosphoric acids, $H_nP_nO_{3n}$ [62]. The acidity increases during this endothermic condensation process.

The contents of the individual polyphosphoric acids present in a concentrated phosphoric acid mixture for various P_4O_{10} concentrations are compiled in Table 5.

Table 5. Percentage contents of individual polyphosphoric acids in a concentrated polyphosphoric acid mixture as a function of P_4O_{10} content [63]

Diphosphoric acid [2466-09-3], pyrophosphoric acid, $H_4P_2O_7$, M_r 177.98, exists in two crystalline modifications with *mp* 54.3 and 71.5 °C. It is readily soluble in water and is converted to orthophosphoric acid, especially upon boiling or in the presence of strong acids. Pure pyrophosphoric acid cannot be obtained by concentration of orthophosphoric acid or by addition of dry P_4O_{10} to the latter (cf. Table 5). It can be prepared from sodium pyrophosphate by ion exchange, or by reaction of insoluble lead pyrophosphate with hydrogen sulfide.

Unlike monophosphoric acid, aqueous solutions of pyrophosphates do not give a yellow precipitate with silver nitrate but a white one. Compared with metaphosphoric acids, which also form a white precipitate, pyrophosphate differs in that it does not coagulate albumin.

Polyphosphoric and Metaphosphoric Acids. In low-molecular, linear polyphosphoric acids (n = 2 – 15) such as tetraphosphoric acid, $H_6P_4O_{13}$,

each phosphorus atom bears a strongly acidic OH group. In addition, the two terminal P atoms are each bonded to a weakly acidic OH group. Cyclic metaphosphoric acids, $H_nP_nO_{3n}$, which are formed from low-molecular polyphosphoric acids by ring closure, have a comparatively small number of ring atoms (n = 3 – 8). Each P atom in the ring is bound to one strongly acidic OH group, i.e., all H atoms are equally acidic.

In high-molecular polyphosphoric acids, $H_{n+2}P_nO_{3n+1}$ (n = 16 – 90), the two terminal H atoms exhibit only low acidity and cannot be replaced by metal atoms. The composition of these acids are close to that of cyclic metaphosphoric acids $H_nP_nO_{3n}$. Upon continual concentration they are initially converted to cross-linked chain structures. These are further transformed from a two-dimensional network to three-dimensionally cross-linked, glassy metaphosphoric acid [62], [64].

Production. Polyphosphoric acid can either be produced from wet phosphoric acid by evaporative concentration, or thermally by combustion of elemental phosphorus.

Wet phosphoric acid is concentrated by direct heating with hot gases in reactors lined with carbon bricks [65] or by indirect heating under vacuum [66]. In the former process, the heating gas is usually injected below the acid surface.

Concentration of wet phosphoric acid also improves its transportability. Commercial wet phosphoric acid with ca. 50 % P_2O_5 contains relatively high concentrations of impurities, which deposit on pipes and containers unless during shipment and storage the acid is constantly agitated. Because polyphosphoric acid has a higher lime binding strength, the impurities are held in solution and cannot deposit.

Phosphoric acid plants in which combustion of phosphorus and absorption of P_2O_5 vapors are performed separately are best suited to the thermal production of polyphosphoric acid (see TVA process, TVA Process). An externally water-cooled tower made of stainless steel is used for combustion. A hydration tower, also made of stainless steel, cooled externally with water and internally with recycled acid, is used for the absorption of P_2O_5 mist. The phosphoric acid recycled in the hydration tower can be kept at the concentration of the desired polyphosphoric acid if an appropriately intensive cooling facility is available [67]. A polyphosphoric acid plant differs from an orthophosphoric acid plant by more expensive cooling and circulation equipment because, in contrast to orthophosphoric acid production, water evaporation cannot be used as a contribution to cooling capacity during production of polyphosphoric acid, and the viscosity of polyphosphoric acid is much higher than that of orthophosphoric acid.

In another process, polyphosphoric acid is produced in a tower in which phosphorus is combusted and P_2O_5 mist is absorbed (cf. IG process, IG Process). The tower consists of two sections of different diameters so that a step is formed at the joint, which serves as an acid collection cup. A second collection cup is located below the tower.

The tower walls are protected by two phosphoric acids of different concentrations. In the upper section, polyphosphoric acid containing 76 % P_2O_5 flows from an overflow cup down the tower walls. In the lower section, polyphosphoric acid with 84 % P_2O_5 is sprayed onto the tower walls. Both acid recycle streams are cooled by cooling facilities. It is advantageous to operate this plant in combination with other production units for phosphoric acid. Such a plant can for instance use the flue gases from production of dry P_2O_5 and pass its own flue gases on to the absorption section of the orthophosphoric acid plant [68].

Commercial Products and Uses. The fertilizer industry was the largest area of application of polyphosphoric acids until about 1973. Especially in the United States, large amounts of ammonium phosphate, triple superphosphate, and liquid fertilizers were made from polyphosphoric acids. This application has declined strongly. Polyphosphoric acid is used in organic chemistry as an acidic catalyst and dehydrating agent as well as for cyclization reactions [69].

[Top of Page]

3. Phosphates

Thomas Staffel and Thomas Klein

The salts of phosphoric acid are technically and commercially the most important group of phosphorus compounds besides the acid itself. According to their applications, fertilizer phosphates (⟶ Metals, Surface Treatment) are distinguished from other commercial phosphates discussed here. While the use of phosphates as fertilizers started in the mid-1800s with the introduction of mineral fertilization, other phosphates were used industrially at the turn of the century only sporadically. They attained greater commercial importance since ca. 1930 with the production of condensed phosphates, especially for the detergent industry.

Structure and Nomenclature. All phosphate salts contain PO_4 units as characteristic structural element. The central phosphorus atom is surrounded by a tetrahedral arrangement of oxygen atoms. The tetrahedral symmetry is based on formation of sp^3 hybrid orbitals on the phosphorus atom, which is linked to the four oxygen atoms by sigma bonds. The P – O bond strength is enhanced by π bonding with participation of phosphorus *d* orbitals. Ideal tetrahedral structure with a theoretical O – P – O bond angle of 109°28′ can only be expected for a free PO_4^{3-} ion. In most crystalline phosphates, especially in condensed phosphates, deformation of the PO_4 tetrahedra occurs due to unsymmetrical lattice forces, so that bond angles of 95 – 125° are found. The bond lengths are shorter than expected for a single bond due to the double bond character. Average P – O distances of 154 pm are found.

Polymers with chain, ring, or cross-linked structure are obtained by linkage of several PO_4 tetrahedrons via common oxygen atoms. The tetrahedra are joined exclusively by vertex sharing.

Since polyphosphates are prepared from acidic monophosphates by condensation, they are usually referred to as condensed phosphates. Three types of condensed phosphates are distinguished according to the structure of their anions [62]: polyphosphates with chain structure, cyclic metaphosphates, and cross-linked or ultraphosphates with branched chains and/or rings.

All phosphate salts can be described as combinations of oxides, e.g., $Na_2H_2P_2O_7$ as $Na_2O \cdot H_2O \cdot P_2O_5$. The ratio of cationic oxides (Na_2O, CaO, H_2O) to P_2O_5 is characteristic for the individual structural types. Table 6 shows the structural relations and classifications.

Table 6. Structure and nomenclature of phosphates

Oxide ratio	Group name	General formula	Anion structure	Examples
3	monophosphate (isolated PO_4 tetrahedra)	$M^I_3PO_4$		Na_3PO_4 trisodium phosphate $Ca(H_2PO_4)_2$ calcium dihydrogen phosphate
> 1–2	polyphosphates (chain form)	$M^I_{n+2}P_nO_{3n+1}$		$Na_2H_2P_2O_7$ disodium dihydrogen phosphate $Na_5P_3O_{10}$ pentasodium triphosphate
1	metaphosphates (cyclic)	$M^I_3P_nO_{3n}$		$Na_3(PO_3)_3$ sodium trimetaphosphate $Na_6(PO_3)_6$ sodium hexametaphosphate
<1[a]	cross-linked or ultraphosphates (branched chains or rings)			CaP_4O_{10} $Ca_2P_6O_{17}$

[a] Special cases: isopolyphosphate, oxide ratio >1 to 2; isometaphosphate, oxide ratio 1.

The polyphosphates ($M^I_{n+2}P_nO_{3n+1}$) are named according to the IUPAC rules as di-, tri-, tetraphosphates, etc. Frequently, the older designations pyro-, tripoly-, tetrapolyphosphate, etc., are also still used. Moreover, it is customary to distinguish between chromatographically separable, oligomeric phosphates with $n < 12$ and high-molecular polyphosphates with n = 13 to > 10 000. Both glassy and crystalline forms are known in both groups. While mixtures of various chain lengths are always present in glassy phosphates, crystalline oligomeric phosphates are uniform with regard to anion size. It is debatable whether crystalline, high-molecular polyphosphates are also uniform [62].

The oxide ratio in metaphosphates, $M^I_nP_nO_{3n}$, is exactly 1. Polyphosphates with very high molecular masses have practically the same oxide ratio, and are therefore often incorrectly called “metaphosphates” (e.g., sodium hexametaphosphate for Graham's salt). According to the newer nomenclature, the term “metaphosphate” is reserved for condensed phosphates with cyclic anions. So far, metaphosphates are known for n = 3 – 8. There is no evidence for the existence of a dimeric anion with n = 2. Although there are indications for the occurrence of ring structures with n > 8 in some phosphate glasses, they have so far not been isolated. Cross-linked or ultraphosphates contain P atoms which are linked with each other via three O atoms. Additional designations are commonly used in special cases: isometaphosphate when a ring is linked with one or more chains, and isopolyphosphate if only branched chains are present. Compounds with rings linked directly or via chains are more specifically called ultraphosphates. Commercially, cross-linked phosphates are not very important. So far, only a few well-defined examples of this structural type are known.

3.1. Sodium Monophosphates

As a tribasic acid, monophosphoric acid (orthophosphoric acid) forms three series of sodium salts, i.e., mono-, di-, and trisodium monophosphate. Besides the anhydrous compounds, defined hydrates and some double salts are known. Table 7 lists the monophosphates characterized in the $Na_2O – P_2O_5 – H_2O$ system.

Table 7. Sodium monophosphates

Compound	Density, g/cm^3	*mp*	Crystal system
NaH_2PO_4	2.36	200 *	
$NaH_2PO_4 \cdot H_2O$	2.04	100	orthorhombic
$NaH_2PO_4 \cdot 2\ H_2O$	1.91	60	orthorhombic

$2\ NaH_2PO_4 \cdot Na_2HPO_4 \cdot 2\ H_2O$			
$2\ NaH_2PO_4 \cdot Na_2HPO_4$			
$NaH_2PO_4 \cdot H_3PO_4$		127 – 131	
Na_2HPO_4	1.10		monoclinic
$Na_2HPO_4 \cdot 2\ H_2O$	2.07	95	orthorhombic

** Transformation.

Figure 17 shows the solubility of sodium monophosphates as a function of temperature. As salts of a tribasic acid whose dissociation decreases greatly from the first to the third stage ($pK_1 = 2.15$, $pK_2 = 7.1$, $pK_3 = 12.4$), alkali-metal monophosphates exhibit buffer properties.

Figure 17. Solubility of sodium monophosphates [70]

Sodium monophosphates are usually produced by neutralization of phosphoric acid with soda ash or caustic soda. The latter is predominantly used in Germany, while in the United States, the less expensive soda ash prevails. The basicity of sodium carbonate is insufficient for the formation of trisodium phosphate, so that caustic soda must be used in this step. The phosphates crystallize from the solutions as hydrates and are separated by centrifugation. Anhydrous salts are obtained by dehydration in rotary dryers or directly from the solutions by spray drying or in rotary kilns.

Both thermal phosphoric acid and the cheaper wet phosphoric acid are used as starting materials. The very pure thermal phosphoric acid is generally used in the production of food-grade phosphates.

Monosodium dihydrogenmonophosphate [7558-80-7], monosodium phosphate, NaH_2PO_4, M_r 119.98, crystallizes in anhydrous form and as the mono- and dihydrates. The pH of a 1 % aqueous solution is 4.5. The anhydrous salt decomposes upon heating from 169 °C to 240 °C, with elimination of water and formation of $Na_2H_2P_2O_7$.

Thermal phosphoric acid is used preferentially for production of monosodium phosphate. Wet phosphoric acid is less suitable because the impurities are only partially precipitated in the neutralization with soda ash or caustic soda up to the first stage, so that additional recrystallization would be required to purify the phosphate. The dihydrate and the anhydrous salt are the usual commercial forms. Due to its acidity, monosodium phosphate is used as phosphating agent for metal surface treatment and as component of acidic detergents. Mixtures of mono- and disodium phosphate are used as buffers in the pH range 5 – 8, especially in textile finishing processes. In water conditioning, monosodium phosphate is frequently added for correction of the alkalinity of water purified by ion exchange. Monosodium phosphate serves as a mineral supplement for feeds and as a pH stabilizer for soups and juices in the food area. Monosodium phosphate is used as raw material for the production of disodium diphosphate and higher condensed phosphates.

Disodium hydrogenmonophosphate [7558-79-4], disodium phosphate, Na_2HPO_4, M_r 141.97, crystallizes in the anhydrous form as well as with 2, 7, 8, and 12 H_2O. The crystal structure is composed of HPO_4^{2-} anions in a hexagonal close-packed arrangement, in which Na^+ cations occupy octahedral and tetrahedral interstices.

Both thermal and purified wet phosphoric acid are used in production. In a process developed in the 1980s, acidic phosphate solution ($CaHPO_4$ in the presence of H_3PO_4) is reacted with $NaHSO_4$, whereby purification occurs through precipitation of gypsum [71]. Neutralization with NaOH is carried out in a second stage. Salts are obtained from the neutralized solutions by evaporation, crystallization, and centrifugation. The desired hydrate is obtained by appropriate temperature control. The anhydrous product is also produced by dehydration of the solution in a spray drying tower. Careful temperature control is required to avoid formation of tetrasodium diphosphate.

Anhydrous Na_2HPO_4, $Na_2HPO_4 \cdot 2\ H_2O$, and $Na_2HPO_4 \cdot 12\ H_2O$ are the commercial forms. Disodium phosphate is blended with monosodium phosphate to prepare buffer mixtures. Other applications are treatment of boiler feedwater (see Trisodium Monophosphate Uses.), addition to detergents and cleansers, and preparation of mineral feedstuff supplements. In the food industry, disodium phosphate is used in the production of evaporated milk and other concentrated dairy products such as milk powder and cream to prevent coagulation on heating. It is also used as a component of instant desserts and puddings. Another application of Na_2HPO_4 is for silk weighting in the textile industry. Disodium phosphate is used as starting material for the production of tetrasodium diphosphate and, together with monosodium phosphate, for the production of higher condensed phosphates.

Trisodium monophosphate [7601-54-9], trisodium phosphate, Na_3PO_4, M_r 163.95, crystallizes in the anhydrous form and with 1/2, 6, 8, or 12 H_2O. The pH of a 1 % aqueous solution is ca. 11.9. The dodecahydrate always crystallizes from aqueous solutions with an excess of NaOH. Products with compositions ranging from $Na_3PO_4 \cdot 12\ H_2O \cdot ¼$ NaOH to $Na_3PO_4 \cdot 12\ H_2O \cdot {}^1/_7$ NaOH are obtained, depending on the composition of the starting solution and the temperature. The stoichiometric compound $Na_3PO_4 \cdot 12\ H_2O$ is unstable in aqueous solution and can therefore only be obtained by isothermal hydration of the other hydrates, which are free of NaOH. Depending on composition, the dodecahydrate dissolves at 70 – 74 °C in its water of hydration.

In addition to NaOH, several other sodium compounds such as NaOCl, NaCl, $NaNO_3$ form double salts with trisodium phosphate [72]. Of these, the addition compound with sodium hypochlorite (chlorinated trisodium phosphate) is commercially important.

Production. Trisodium phosphate is mainly produced as the dodecahydrate by complete neutralization of phosphoric acid with caustic soda or soda ash and subsequent crystallization. Since neutralization with soda ash does not proceed beyond the stage of the disodium salt, caustic soda must be added to complete the reaction. Frequently, mother liquors of mono- or disodium phosphate production or crystalline disodium phosphates are used as starting materials. In another process, trisodium phosphate is obtained by digestion of the phosphate-rich neutralization sludges, which accumulate in the purification of wet phosphoric acid by precipitation, with caustic soda and with addition of water glass [73]. In this process, aluminum and iron phosphates are converted to $Fe(OH)_3$ and $Na_2Al_2SiO_6$ and separated from the Na_3PO_4 solution by filtration. On a commercial scale, it is also possible to react $CaHPO_4$ with H_2SO_4 to form $CaSO_4$ and H_3PO_4. Caustic soda can be added to the latter to give $Na_3PO_4 \cdot 12\ H_2O$ [74].

For production of the dodecahydrate, the most widely used form, the solutions are concentrated. The solid salt is obtained in the form of flakes on cooled rollers or as powder in spray towers. Cooling the solution gives the salt as needles, which are centrifuged and dried with hot air. The anhydrous salt is mostly produced from the molten dodecahydrate by spray drying.

The dodecahydrate tends to cake during storage. In order to obtain a free-flowing and storage-stable product it is mixed with hydrophilic materials such as magnesium salts or silicates [75].

Uses. The most widely used commercial product is the dodecahydrate, in the form of flakes, needles, or spray dried powder. The anhydrous salt is marketed as a powder. Due to hydrolysis, trisodium phosphate reacts strongly alkaline in aqueous media, and thus causes saponification of fats.

$$PO_4^{3-} + H_2O \rightleftharpoons HPO_4^{2-} + OH^-$$

Due to its fat- and dirt-solving properties it is used as an industrial cleansing agent for machine parts, occupational clothing, milk cans, dishes, and bottles. Trisodium phosphate is also used for surface treatment of aluminum to obtain a gloss effect.

Trisodium phosphate is the standard agent for water softening, especially of feedwater for steam boilers. Ions such as Ca^{2+} or Mg^{2+} react with trisodium phosphate to form water insoluble phosphates as voluminous, sludgy precipitates, which are removed by sedimentation or filtration before the purified water enters the boiler:

$$3\,Ca(HCO_3)_2 + 2\,Na_3PO_4 \rightarrow Ca_3(PO_4)_2 + 6\,NaHCO_3$$

$$3\,MgSO_4 + 2\,Na_3PO_4 \rightarrow Mg_3(PO_4)_2 + 3\,Na_2SO_4$$

Trisodium phosphate is also used to remove residual hardness from water treated by ion exchange or precipitation processes. An advantage is that the phosphate precipitates do not form deposits and are easily removed. Moreover, a small excess of phosphate in the boiler water decreases corrosion by formation of a strongly adhering protective layer of iron phosphate. For complete softening, 14 g $Na_3PO_4 \cdot 12\,H_2O$ is needed for 1° d carbonate hardness (German hardness scale), and 42 g for 1° d non-carbonate hardness per cubic meter of water.

Chlorinated trisodium phosphate, $Na_3PO_4 \cdot ¼\,NaOCl \cdot 11\,H_2O$; the pH of a 1 % aqueous solution is ca. 11.8. The addition compound of trisodium phosphate with sodium hypochlorite is usually produced by the same process as trisodium phosphate itself but with replacement of a part of the required caustic soda by NaOCl. Special processes for production of a storage-stable product are described in the patent literature [76]. Due to its active chlorine content, chlorinated trisodium phosphate has bleaching and bactericidal properties in addition to the fat- and dirt-solving effect resulting from its high alkalinity. Therefore, it is used as a disinfecting cleanser. The product has gained considerable importance especially in the United States where it is used in detergents for automatic dishwashers and in the sanitary area. However, in Europe it is only of minor importance.

Sodium monofluorophosphate [10163-15-2], Na_2PO_3F, M_r 144, is a white odorless powder. Its solubility in water is 25 g per 100 g H_2O at 25 °C. The $NaPO_3$ – NaF phase diagram (Fig. 18) shows polymorphic transformations of Na_2PO_3F at 370 °C and 410 °C. The salt melts congruently at 635 °C; prolonged heating of Na_2PO_3F gives pyrophosphate. Hydrolysis occurs in the presence of moist air or in solution:

$$Na_2PO_3F + H_2O \rightleftharpoons HF + Na_2HPO_4$$

Figure 18. Phase diagram of the $NaPO_3$ – NaF system [77]

Structure. The NMR spectrum of sodium monofluorophosphate shows that the monofluorophosphate anion has the structure of the tetrahedral orthophosphate group in which an oxygen atom is substituted by a fluorine atom [78].

The PO_3F^{2-} ion is isoelectronic with SO_4^{2-} and hence possesses similar chemical properties to the sulfate group.

Production. There are two main processes used in the commercial production of Na_2PO_3F. The most common process involves the reaction of sodium fluoride with sodium (meta)phosphates by melting at the eutectic point [79]; the reaction is exothermic:

$$NaF + NaPO_3 \rightleftharpoons Na_2PO_3F$$

Since the molten mixture of Na_2PO_3F, NaF, and $NaPO_3$ can react with many metals and metal oxides, the choice of reactor material is important. Platinum, platinum alloys, and glass – carbon composites are usually used for the reactor walls [80-82]. Other reactor materials used are graphite [81], silver, and iron.

With oligophosphates the rate of reaction increases with increasing chain length. Cyclic tri- and tetrametaphosphates react even faster. Maddrell's salt can also be used to prepare Na_2PO_3F, as can a mixture of tetrasodium pyrophosphate and phosphorus pentoxide [80], [83]:

$$Na_4P_2O_7 + 4\,NaF + P_2O_5 \rightleftharpoons 4\,Na_2PO_3F$$

The second process for the production of Na_2PO_3F involves the reaction of tetrasodium pyrophosphate or disodium phosphate with preheated hydrogen fluoride at 200 – 460 °C in a nickel or aluminum reactor [84], [85]:

$$Na_4P_2O_7 + 2\,HF \rightleftharpoons 2\,Na_2PO_3F + H_2O$$

$$Na_2HPO_4 + HF \rightleftharpoons Na_2PO_3F + H_2O$$

Uses. Sodium monofluorophosphate is used in applications where fluoride ions are needed for human physiological processes. It has lower toxicity than sodium fluoride [187]. Sodium monofluorophosphate is mostly used in toothpastes, where it serves as a carrier for the fluoride ion, which is a caries prophylactic [86]. It performs a similar function in pharmaceuticals for the treatment of osteoporosis. In special concrete materials, sodium monofluorophosphate is used as a setting retarder [188], [189].

Analysis. Detection of PO_3F^{2-} is based on the fact that Ag_2PO_3F, unlike AgF, is insoluble in water. Hence determination of PO_3F^{2-} can be carried out gravimetrically or complexometrically. Detection of PO_3F^{2-} by ion chromatography is also possible [86].

3.2. Condensed Sodium Phosphates

Condensed sodium phosphates are formed by condensation of two or more hydrogenphosphate units to form chain or cyclic phosphates, with elimination of water, usually thermally. For example, tetrasodium diphosphate (commercial name, sodium pyrophosphate) is formed from two moles of Na_2HPO_4 upon heating:

The composition and structure of the products formed depend on temperature and the $Na_2O : P_2O_5$ ratio. Figure 19 shows the possible products by means of the phase diagram.

Figure 19. Phase diagram of the Na_2O – P_2O_5 system [87]

3.2.1. ***Properties***

Condensed sodium phosphates are all water soluble except for high-molecular, crystalline salts such as Maddrell's and Kurrol's salts. The acids from which polyphosphates are derived contain two types of OH groups that differ greatly in their degree of dissociation. Each P atom bears a strongly acidic OH group, while the terminal P atoms additionally have a weakly acidic OH group. Since with increasing chain length the number of strongly acidic groups becomes very large compared with the two weak terminal groups, higher condensed polyphosphates react like salts of a strong, monobasic acid. The buffer capacity, strongly pronounced in monophosphates, decreases with increasing chain length and is absent in higher condensed products such as Graham's salt. Accordingly, the pH of 1 % aqueous solutions of “neutral salts” decreases from trisodium phosphate (11.5) through tetrasodium phosphate (10.2) and pentasodium phosphate (9.7) to Graham's salt (6.0). Due to their cyclic structure, metaphosphates contain no terminal acid groups. Consequently, they react in aqueous solution like salts of strong, monobasic acids.

Hydrolytic Decomposition. In aqueous solution, polyphosphates decompose hydrolytically in reversal of the condensation reaction, eventually forming monophosphates [88]. The decomposition rate is strongly dependent on the temperature and pH of the solution. It usually increases with increasing temperature and decreasing pH. At pH 7 and 25 ° C the half-life for the degradation into shorter chains has been calculated to be in the range of 3.5 years [190].

The decomposition is influenced by metal ions. Alkali metal, alkaline earth metal, Al^{3+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+} and Zn^{2+} cations retard the hydrolysis of phosphates in acid media. The efficiency increases from univalent to trivalent ions and within the first group of the periodic table from bottom to top. In alkaline solution, however, metal cations accelerate the hydrolysis of phosphates and the catalytic effectiveness decreases with increasing ionic radius [191]. The degree of acceleration increases in the following order :

$$Al^{3+} > Mg^{2+} > Ca^{2+} > Sr^{2+} > Ba^{2+}$$

Sodium triphosphate in aqueous solution has a half-life of more than a year at pH 8 and room temperature. However, its half-life is in the range of minutes at pH 3 and 100 °C. Under neutral to alkaline conditions, decomposition mainly involves successive cleavage of monosphosphate units from the chain ends, whereas in strongly acidic medium, internal chain cleavage, with formation of low molecular mass fragments, also occurs. In addition to cleavage of phosphate units from the chain ends, a second decomposition reaction occurs for polyphosphates of higher molecular mass, which is accelerated in acidic solution and in which metaphosphates are formed initially [62].

In neutral aqueous solutions at room temperature metaphosphates are also very stable. At elevated temperature and low pH they decompose rapidly, giving initially the corresponding polyphosphates, which, however, themselves undergo rapid hydrolysis to give monophosphates. The metaphosphate rings are also cleaved practically quantitatively in alkaline solution, albeit at a relatively slow rate.

In acidic solution, linear oligomers are hydrolyzed faster than cyclic oligomers, except for cyclotriphosphate. For the linear phosphates, the rate gradually increases with increasing degree of polymerization. In alkaline solution, large differences are observed between the rates for cyclic (fast hydrolysis) and linear oligomers (slow). However, with increasing degree of polymerization the differences become smaller. The first-order hydrolysis rate constants for cyclic and linear penta- and heptaphosphate at 50 °C in 0.1 mol/L HCl are 0.128 h^{-1} (*cyclo*-P_5), 0.764 h^{-1} (P_5), 0.136 h^{-1} (*cyclo*-P_7), 1.54 h^{-1} (P_7), and at the same temperature in 0.5 mol/L NaOH: 0.0166 h^{-1} (*cyclo*-P_5), 6.7×10^{-3} h^{-1} (P_5), 7.4×10^{-3} h^{-1} (*cyclo*-P_7), 0.0234 h^{-1} (P_7) [192].

Tri- and tetrametaphosphate can be converted completely to the corresponding polyphosphates with caustic soda because the latter are comparatively stable under these conditions. However, a similar preparation of higher polyphosphates is not possible because the stability of metaphosphates increases greatly with ring size, so that the polyphosphates are largely decomposed before all the metaphosphate is cleaved [62], [89].

The hydrolytic degradation is easily monitored by ^{31}P NMR spectroscopy or ion chromatography. The ^{31}P NMR spectra of polyphosphates show two major peaks, with chemical shifts in the range of 5 – 10 and 15 – 20 ppm. The high-field signal can be attributed to the end-group phosphate units, and the other signal to the middle groups [193]. The middle to end group integral ratio is related to the average degree of polymerization, which decreases during hydrolysis.

Ion chromatography of polyphosphate solutions can be performed with a anion-exchange column (Dionex AS7) and gradient elution. The eluent is a NaOH/NaCl solution whose content of NaCl is increased during elution. Detection by hydrolysis to orthophosphoric acid and post-column derivatization (as molybdatovanadatophosphate complex) has proved best [194]. Each polyphosphate species (e.g., pentaphosphate, hexaphosphate, etc., up to P_{50}) gives a peak whose integral corresponds to the concentration. Hence this method allows a detailed look at the alteration of the concentration of distinct molecules. Figure 20 gives an example for a highly condensed polyphosphate.

Figure 20. Ion chromatograph of a highly condensed polyphosphate $Na(PO_3)_n$ with a P_2O_5 content of 68 % [195]

Cation-Binding Capacity. The cation-binding capacity of polyphosphates is of considerable commercial importance. This term denotes the capability to bind cations of multivalent metals, especially of Ca, Mg, and Fe, and to hold them in solution such that they can no longer be detected with the usual precipitation reagents. For example, calcium ions are not precipitated by oxalate in an aqueous solution containing sodium triphosphate. Numerous investigations have shown that the effect of polyphosphates is not due to the formation of well-defined, soluble complexes but that they behave like soluble ion exchangers [90], [91]. In aqueous solution, polyphosphates are at most 30 % dissociated [92], although all OH groups of the corresponding polyacids, apart from the two terminal groups, can be titrated as strong acids.

Bonding of the cation is primarily attributed to electrostatic attraction by the negatively charged polyanions. In addition, formation of relatively stable chelates, in which the cations are bonded to several PO_3 groups in the flexible polyphosphate chain, also must be assumed [62]. Since multivalent cations are bound much more strongly than the monovalent ions of alkali metals, the latter can readily be exchanged for alkaline earth or heavy metal ions. This exchange and binding capacity is used for numerous purposes to mask and inactivate interfering cations.

Various methods are used to determine the exchange capacity. The lime-binding capacity or lime-binding value denotes the amount of CaO kept in solution by a specific amount of alkali-metal polyphosphate in the presence of reagents which precipitate Ca^{2+}. For the determination, a predetermined amount of polyphosphate is titrated with $CaCl_2$ in the presence of sulfate ions to the onset of turbidity. Alternatively, the end point is determined by formation of sparingly soluble calcium polyphosphate without addition of calcium-precipitating anions [93].

The lime-binding capacity of polyphosphates increases with increasing chain length up to n = 8. For higher degrees of condensation it remains essentially unchanged. Figure 21 shows the amount of phosphate which is necessary to prevent precipitation of an insoluble calcium compound (e.g., calcium oxalate) as a function of chain length. The lime-binding capacity is also dependent on concentration, pH, temperature, and the presence of electrolytes [94]. In contrast to polyphosphates, cyclic metaphosphates exhibit only minor exchange capability toward multivalent cations.

Figure 21. Lime-binding capacity of polyphosphates as a function of chain length

The figure shows the amount of polyphosphate which is necessary to complex all calcium ions in 10 L of water with a hardness of 10° dH

Colloidal Behavior. Many applications of polyphosphates are based on colloidal effects. These are secondary effects because polyphosphates themselves exhibit no colloidal properties in pure, aqueous solution. Essentially, the effect is due to adsorption of multiply charged polyphosphate anions on suspended or emulsified particles, electrical charging of the latter, and consequent change of the physicochemical characteristics [95].

The dispersive action of polyphosphates is one of the most prominent effects. Viscosity reduction, which always occurs concurrently, is directly related to this effect. For

instance, stiff, tenacious pastes such as blanc-fixe ($BaSO_4$) can be converted to stable, free-flowing suspensions by addition of small amounts of Graham's salt. Kaolin suspensions of high solids content and low viscosity can be prepared with small amounts of polyphosphate.

The improvement of the soil antiredeposition capacity in the laundry process by polyphosphates can also be regarded as suspension stabilization. Although polyphosphates themselves are not surface-active and thus are not really emulsifiers, they increase the surface activity of wetting agents. Presumably, the effect is due to a dispersion of the surface-active substances.

The peptization of proteins is another colloid chemical effect. It plays an important role in the production of processed cheese and in meat processing. Protein is partially digested by polyphosphate and converted to a sol.

In many cases the dispersing effect of polyphosphates is due to adsorption and is supplemented by stabilization due to elimination of interfering factors (calcium binding).

3.2.2. *Sodium Diphosphates*

The following sodium diphosphates (pyrophosphates) are known as crystalline compounds [96]:

$NaH_3P_2O_7$	$Na_3HP_2O_7 \cdot H_2O$
$Na_2H_2P_2O_7$	$Na_3HP_2O_7 \cdot 9\ H_2O$
$Na_2H_2P_2O_7 \cdot 6\ H_2O$	$Na_4P_2O_7$
$Na_3HP_2O_7$	$Na_4P_2O_7 \cdot 10\ H_2O$

Of these, only disodium diphosphate and tetrasodium diphosphate are produced on a large scale.

Disodium dihydrogendiphosphate [7758-16-9], disodium diphosphate, acidic sodium pyrophosphate, $Na_2H_2P_2O_7$, M_r 221.97, *d* 2.31. Its solubility in water is 13 g $Na_2H_2P_2O_7$/100 g H_2O at 20 °C, and 20 g at 80 °C. The pH of a 1 % aqueous solution is 4.1. The usual commercial product is the anhydrous, nonhygroscopic salt in powder form. The hexahydrate, $Na_2H_2P_2O_7 \cdot 6\ H_2O$, *d* 1.85, crystallizes from aqueous solution below 27 °C. Above this temperature, it is converted to the anhydrous form.

Disodium dihydrogendiphosphate is produced from sodium dihydrogenmonophosphate by heating at 200 – 250 °C:

$$2\,NaH_2PO_4 \rightarrow Na_2H_2P_2O_7 + H_2O$$

Careful control of reaction temperature and time is required to achieve complete conversion of the monophosphate and to avoid formation of higher condensed phosphates. Reaction times of 1 – 6 h at 215 – 245 °C are used [97]. The degree of condensation can be influenced by regulating the partial pressure of water vapor [98].

Usually, monophosphate is converted to diphosphate continuously in rotary kilns. Smaller plants also use batch processes with plate dryers or electrically heated pans.

A monophosphate solution made from phosphoric acid and caustic soda in situ is used in the so-called “return” process. The crystal slurry obtained by evaporation is combined with recycled material in a twin screw and charged to a rotary dryer [99].

In another process, NaH_2PO_4 solution is spray dried at 140 – 195 °C, giving 10 – 40 % $Na_2H_2P_2O_7$. Subsequent calcination at 200 – 220 °C gives pure $Na_2H_2P_2O_7$ [100].

Disodium diphosphate is used as a (tropically stable) acid carrier in baking powder, for improvement of flow properties in flour, for pH regulation, and in dental care products for prevention of tartar formation.

Tetrasodium diphosphate [7722-88-5], tetrasodium pyrophosphate, neutral sodium pyrophosphate, $Na_4P_2O_7$, M_r 265.91, *d* 2.50, *mp* 985 °C. Its solubility in water is 5 g $Na_4P_2O_7$/100 g H_2O at 20 °C and 35 g at 80 °C. The pH of a 1 % aqueous solution is 10.4. The usual commercial product is the anhydrous salt in the form of a white, nonhygroscopic powder. However, in contact with moist substances it acts as a drying agent with formation of $Na_4P_2O_7 \cdot 10\ H_2O$.

The decahydrate, $Na_4P_2O_7 \cdot 10\ H_2O$, *d* 1.83, *mp* 79.5 °C (with loss of H_2O), is also marketed but on a much smaller scale. It crystallizes from aqueous solution below the melting point. Anhydrous $Na_4P_2O_7$ is known in five different modifications with transition temperatures between 400 and 545 °C. Only the low-temperature form is stable below 400 °C.

Tetrasodium diphosphate is produced by calcination of disodium hydrogenphosphate at 300 – 900 °C:

$$2\,Na_2HPO_4 \rightarrow Na_4P_2O_7 + H_2O$$

In the two-stage process, a concentrated monophosphate solution is dehydrated to give anhydrous disodium hydrogenphosphate in a spray drying tower and subsequently condensed to diphosphate in a rotary kiln. For improvement of the heat economics, the hot off-gases from the second stage can be used for spray drying. In another process, phosphoric acid and caustic soda are metered separately into a spray drying tower in order to utilize the heat of neutralization [101].

Both rotary kilns and spray drying towers are used in the single-stage production of $Na_4P_2O_7$. In the rotary kiln process, the phosphate solution is sprayed onto a bed of already formed, solid monophosphate (return process). A single-stage spray tower process is described below (see Pentasodium Triphosphate Properties.). Generally, the processes for production of sodium triphosphate can also be used for sodium diphosphate.

Tetrasodium diphosphate is used in detergents and cleansers, in metal surface treatment, and in oil well drilling fluids for viscosity adjustment. In the food area, $Na_4P_2O_7$ is used as a component of cold puddings and ice cream for regulating the consistency. The stabilization of toothpastes based on calcium hydrogenphosphate is another important application.

3.2.3. *Pentasodium Triphosphate*

Pentasodium triphosphate [7758-29-4], sodium triphosphate, sodium tripolyphosphate, is one of the commercially most significant phosphorus compounds.

Properties. Pentasodium triphosphate, $Na_5P_3O_{10}$, M_r 367.93; solubility of the hexahydrate in water, 14.6 g $Na_5P_3O_{10}$/100 g H_2O at 20 °C, 23.7 g at 80 °C; pH of a 1 % aqueous solution, 9.7.

Pentasodium triphosphate exists in two anhydrous modifications, i.e., the low-temperature (LT) form (*d* 2.57, monoclinic) and the high-temperature (HT) form [*d* 2.62, monoclinic, *mp* 622 °C (decomp.)], and as the hexahydrate, $Na_5P_3O_{10} \cdot 6\ H_2O$ (*d* 2.12, triclinic). In the technical literature, the HT form is often referred to as form II, and the LT form as form I. The LT form is converted completely to the HT form on heating to 500 °C. However, the HT form is transformed to the LT form only very slowly on tempering below 400 °C (transition temperature, 417 ± 8 °C [102]). At 622 °C the anhydrous salt decomposes to a melt and crystalline $Na_4P_2O_7$ (see also Fig. 19). Above 865 °C a homogeneous melt is obtained, which on rapid cooling yields a glassy product. This can be converted to the crystalline modifications by heating under specific conditions [103], [104].

The two modifications differ in their reaction with water. Both forms are metastable in water and undergo complete conversion to the hexahydrate in an exothermic reaction. However, the hexahydrate is formed much faster from the HT modification than from the LT form. The anhydrous modifications are more soluble than the hexahydrate. Therefore, on dissolution a concentration of ca. 32 % $Na_5P_3O_{10}$ is attained initially which is considerably higher than that of a solution in equilibrium with the hexahydrate (ca. 13 % $Na_5P_3O_{10}$). This occurs especially on dissolution of the LT form, from which the hexahydrate is formed at a slower rate.

On heating to 100 – 120 °C, the hexahydrate hydrolyzes to give mono- and diphosphate:

$$Na_5P_3O_{10} \cdot 6\,H_2O \rightarrow Na_3HP_2O_7 + Na_2HPO_4 + 5\,H_2O$$

$$Na_3HP_2O_7 + Na_2HPO_4 \rightarrow Na_4P_2O_7 + NaH_2PO_4$$

On further heating to 140 – 220 °C the hydrolyzed products recondense to form anhydrous $Na_5P_3O_{10}$ in the LT modification. Commercial products contain a mixture of the HT and LT forms, depending on application and processing requirements. Formerly products with a high content of the LT form were preferred for the manufacture of detergent powders, the major application of sodium triphosphate. The reason was that the rapidly hydrated HT form tends to cake during the production of detergent slurries and is thus

more difficult to process. Later it was recognized how much the hydration properties of the triphosphate are also affected by the content of hexahydrate crystal nuclei. Now, the detergent industry tends not to specify certain contents of the two modifications but rather overall hydration characteristics measurable by the heat of hydration as a function of time [105].

Production. Pentasodium triphosphate is usually produced from a mixture of two moles of disodium phosphate and one mole of monosodium phosphate:

$$2\,Na_2HPO_4 + NaH_2PO_4 \rightarrow Na_5P_3O_{10} + 2\,H_2O$$

The reaction is carried out in the temperature range 300 – 550 °C, whereby the reaction temperature determines the LT/HT form ratio. For the production of triphosphate with a minimum content of $Na_4P_2O_7$ and higher condensed polyphosphates, the monophosphates must be present in precise stoichiometric ratio in a homogeneous, finely crystalline mixture. In most cases, a stoichiometrically adjusted monophosphate solution, obtained by neutralization of phosphoric acid with caustic soda or soda ash, is used as starting material. Both single-stage and two-stage processes are used for dehydration of the solution and subsequent condensation to triphosphate.

In the two-stage processes (Fig. 22), the solution is dehydrated in the first stage to give an anhydrous monophosphate mixture. Frequently, partial condensation with formation of diphosphate already occurs in this stage. The actual condensation to triphosphate then follows in the second stage.

Figure 22. Two-stage process for production of pentasodium triphosphate [106]

a) Receiver; b) Heavy-duty pump; c) Combustion chamber; d) Spray tower; e) Wet dust removal from flue gas; f) Sieve; g) Mill; h) Pneumatic conveyor; i) Silo; j) Rotary kiln; k) Flue gas purification; l) Condenser; m) Bucket chain; n) Sieve; o) Bagging scale

Generally, spray dryers are used for dehydration of the monophosphates, and rotary kilns for the conversion to triphosphate. The required energy is supplied by hot gases from a combustion chamber or by an oil or gas flame in the rotary kiln.

A fluidized-bed reactor has also been recommended for the conversion of dried monophosphates to triphosphate [107]. In another process rotary kilns are used in both stages, and a granular end product is obtained by grinding the intermediate product and adding water before calcination [108].

In the single-stage process, rotary kilns or spray drying towers are used. In the Hoechst-Knapsack process (Fig. 23), the monophosphate solution is sprayed at 1 – 2 MPa [109] into a stainless-steel spray tower [110]. Burners, arranged concentrically around the nozzle, generate a flame zone directed conically towards the center of the tower. The sprayed solution moves downward cocurrent with the burner gases and is rapidly dehydrated and converted to triphosphate. Most of the $Na_5P_3O_{10}$ is collected in the tower cone and discharged. Finer particles are separated from the off-gas by cyclones. The off-gas is then further purified by a liquid washing.

Figure 23. Production of pentasodium triphosphate by the Hoechst-Knapsack process [106]

Free-flowing, powdery products are obtained, with triphosphate contents of up to 98 %. The ratio of LT/HT form can be varied over a wide range by controlling the temperature and the water content in the gas phase. Moreover, a particular crystalline form can be obtained by simultaneously spraying seed crystals of the desired modification [111]. Coarse $Na_5P_3O_{10}$ particles (> 0.15 mm) can also be prepared by this seed crystal method. The required crystallites are taken from the residues of the dust filter bag because these flue dusts have favorable spray and suspension characteristics.

In the FMC process, the monophosphate solution is sprayed upwards from nozzles at the bottom of the tower [112]. The particles move upward to the flame zone at the top of the tower and are then carried downward with the hot gas stream.

Single-stage rotary kiln processes are carried out both according to the cocurrent and countercurrent principle. The monophosphate solution is sprayed through a flame directed into the rotary kiln and onto a hot bed of previously calcined material [113]. The product then moves cocurrently with the hot combustion gases to the discharge port and thus is posttempered at a reduced temperature. Advantages of this mode of operation are the avoidance of caking and the possibility to produce a product with a high content of the LT form. The high energy consumption is, however, a disadvantage.

A countercurrent rotary kiln process is described by FMC [114]. The material is conveyed countercurrently to the heating gases, which are generated in a combustion chamber outside of the rotary kiln. This process permits a substantially better heat utilization than the cocurrent process. However, the frequent occurrence of caking at the charging point is a disadvantage.

Numerous suggestions for modification of the commercial processes are found in the patent literature. They are aimed at the preparation of pentasodium phosphate with special application properties and concern especially production of the low-temperature modification [115], [116], attainment of low bulk densities [117], and increase of abrasion resistance [118]. Partially hydrated products are prepared for improvement of the solubility characteristics [119], [120].

Sodium triphosphate hexahydrate is produced by hydration of anhydrous $Na_5P_3O_{10}$. It is important that too high a temperature rise is avoided in the exothermic hydration reaction because the triphosphate anion is cleaved hydrolytically by the water of hydration at elevated temperatures. In the Hoechst-Knapsack process an excess of water is sprayed onto $Na_5P_3O_{10}$ in a rotary kiln. The excess water is evaporated by simultaneously blowing air over the product, dissipating part of the heat of hydration and maintaining the product temperature at 60 – 70 °C [121]. In the Monsanto process crushed ice is used for the hydration of $Na_5P_3O_{10}$ to the hexahydrate [122].

3.2.4. *Higher Condensed Sodium Polyphosphates*

If mixtures of NaH_2PO_4 and Na_2HPO_4 in a ratio > 1 : 2 are heated until the water of constitution is released, a mixture of polyphosphates of different chain lengths is formed. The degree of condensation *n* (average number of P atoms per molecule) is used for characterization. Glassy, amorphous products are obtained by fast cooling of the melts of such mixtures. They are commercially important as glassy phosphates or fused phosphates. Products with *n* = 4 (tetraphosphate) to *n* = 25 (Graham's salt) are produced, depending on the application.

Frequently, the incorrect designation “hexametaphosphate” is used for Graham's salt in the literature, especially in the United States. However, it consists essentially of high-molecular, straight-chain polyphosphates with ca. 6 % trimetaphosphate.

Upon tempering, the glassy Graham's salt is converted to crystalline, high-molecular forms (Kurrol's and Maddrell's salt) or to cyclic sodium trimetaphosphate, $Na_3P_3O_9$. Figure 24 shows the various condensed phosphates which can be obtained from NaH_2PO_4 and their conditions of preparation [62].

Figure 24. Condensed phosphates which can be prepared from NaH_2PO_4 by heating and their interrelationship [62]

Fused phosphates (glassy polyphosphates), $Na_{n+2}P_nO_{3n+1}$, are all hygroscopic and water soluble. The pH depends on the degree of condensation. In 1 % aqueous solutions it ranges from 8.4 for hexasodium tetraphosphate to 4.0 for long-chain polyphosphates (*n* > 20).

High-molecular fused phosphates are produced from acidic monophosphates in tank furnaces lined with zircon mineral bricks (Fig. 25). The average chain length depends on temperature, duration of fusion, and water vapor pressure of the melt. The melt temperatures are 600 – 800 °C, depending on the $Na_2O : P_2O_5$ ratio. The outflowing melt is chilled on water-cooled barrels or drums with formation of glassy clods, which are subsequently broken and ground.

Figure 25. Production of fused phosphate [95]

a) Burner; b) Melting furnace; c) Melt; d) Cooling roller; e) Worm gear; f) Mill

In another process, fused phosphates are obtained directly from elemental phosphorus [123]. Phosphorus and caustic soda are sprayed by air into a spray tower lined with graphite bricks. Molten polyphosphate is formed in the phosphorus flame at 1500 – 1800 °C, accumulates at the tower bottom, and runs onto a cooled drum. About 30 % of the combusted phosphorus is entrained by the off-gas in the form of fused phosphate and small amounts of P_4O_{10}. These are converted to an aqueous solution of sodium phosphate in a downstream wash tower and returned to the combustion tower. The energy required for dehydration of caustic soda and wash solution as well as for production of the polyphosphate melt is supplied entirely by the heat of phosphorus combustion.

A posttreatment of the ground products by addition of Na_2CO_3 or $Na_4P_2O_7$ or by spray coating with alkaline solutions is recommended for decreasing the hygroscopicity [124].

Maddrell's Salt. Crystalline sodium polyphosphate with a chain length of ca. 2000 P units exists in two modifications: the high-temperature triclinic form (*d* 2.669) and the low-temperature form (*d* 2.52). Both are essentially insoluble in water. For application as a polishing compound in fluoridated toothpastes, it is important that formation of water-soluble trimetaphosphate during production is avoided by maintaining a low partial pressure of water vapor. Sodium dihydrogenphosphate is conveyed at a constant rate through a tunnel furnace while the generated water vapor is continuously drawn off [125]. In the Monsanto process, NaH_2PO_4 is compressed into pellets, which are then dehydrated in a rotary kiln at 300 – 460 °C in a hot air stream [126].

Kurrol's Sodium Salt. This crystalline, long-chain sodium polyphosphate is formed from Graham's salt by tempering at 580 – 590 °C: form A, *d* 2.58, monoclinic; form B, *d* 2.56, monoclinic. It has a fibrous structure similar to asbestos and is only sparingly soluble in water. Upon longer storage in water the fibers swell and slowly form a highly viscous solution.

3.2.5. *Sodium Metaphosphates*

Sodium tri- and tetrametaphosphate, $Na_3P_3O_9$ and $Na_4P_4O_{12}$, are the best known examples of cyclic sodium metaphosphates. In addition, metaphosphates with 5, 6, 7, and 8 phosphorus atoms have also been isolated from Graham's salt [127], [128].

Sodium trimetaphosphate can be prepared by cooling of a corresponding polyphosphate melt and subsequent tempering above 350 °C [129] or by condensation of sodium dihydrogen-phosphate with addition of a small amount of ammonium nitrate [130].

Sodium tetrametaphosphate can be prepared by reaction of the corresponding copper salt with Na_2S or by hydrolysis of hexagonal P_4O_{10} with caustic soda [131].

Sodium trimetaphosphate is used as a phosphorylating agent for ascorbic acid [198] to stabilize vitamin C mixtures against thermal decomposition.

3.2.6. *Uses of Condensed Sodium Phosphates*

Water Treatment. Monophosphates form sparingly soluble precipitates with water hardeners and are therefore used as precipitation agents in water softening. However, the water softening effect of condensed phosphates is due to their ion-exchange capacity for cations. The water softening effect and the capability to mask heavy metal ions are utilized in various ways.

For instance, polyphosphates, especially fused phosphates, are used in the *textile industry* for bleaching, dyeing, and textile finishing. In these applications, additional advantages are attained by the other properties of phosphates, e.g., their dispersing capacity [132].

Fused phosphates are also used in *photography* to prevent spots and shadows caused by precipitation of water hardeners and heavy metal ions in the baths.

Fused phosphates are also used in place of monophosphates in the conditioning of *boiler feedwater*. Compared with monophosphates, polyphosphates have the advantage that, after addition to the feedwater, they initially keep the hardeners in solution. The hydrolytic degradation to monophosphates occurs only at elevated temperature in the boiler. Thus, the hardeners are precipitated there and can be discharged as sludge.

Another property of polyphosphates important in practice is their capability, even at very low concentrations, to prevent precipitation of calcium carbonate. This effect is utilized in the phosphate threshold treatment of tap water, e.g., in communal water conduits, in warm water facilities, or in industrial cooling water systems. The required amounts of phosphate, usually 2 – 5 g/m^3 of water, are much lower than the amount necessary for complexation of the hardeners. In this way, the precipitation of calcium carbonate can be completely prevented at moderate temperatures and water hardnesses and normal pH values. At elevated temperatures and higher water hardnesses, crystal growth is hindered to such an extent that no firmly adhering deposits can be formed. It is assumed that growth of the crystal nuclei is stopped or strongly retarded by adsorption of polyphosphate anions [133], [134].

It is important in the threshold process that the phosphate concentration does not exceed a certain limit because otherwise precipitation of sparingly soluble phosphates begins. These can only be redissolved at substantially higher concentration by complexation. Water-soluble, mostly long-chain fused phosphates such as Graham's salt are used in large waterworks. They are added to the water carrying system as a 2 – 5 % solution. Slow-dissolving, glassy calcium sodium polyphosphates are used mostly in smaller works and in private residences. They are charged in form of lumps to a lock installed in the main line or in a bypass, where they dissolve slowly in the passing water [95].

An additional advantage of the phosphate threshold treatment is the anticorrosion effect due to the formation of a firmly adhering, dense, protective layer of iron calcium phosphate. Phosphates also act as corrosion inhibitors for copper, zinc, and aluminum.

Detergents and cleansers (⟶ Cleansing Agents; ⟶ Laundry Detergents) are major applications of polyphosphates. Pentasodium triphosphate, mostly marketed under the name sodium tripolyphosphate (STPP), is by far the most important product. Many industrial cleansers contain 20 – 35 % pentasodium triphosphate as builder. On a much smaller scale, tetrasodium diphosphate is also used for these applications but its significance has declined steadily in the last 10 years. The higher condensed fused phosphates are also used, i.e., in specialty cleansers and personal hygiene preparations.

Triphosphate performs several functions in the laundry process. Primarily, it softens the water by masking alkaline earth metal ions and preventing their deposition on the fabric. In addition, triphosphate prevents precipitation in the washing machine, especially on the heating elements [135]. Furthermore, the pronounced dispersing capacity of triphosphate and its emulsion stabilizing effect are important in the laundry process. Condensed phosphates increase the surface activity of wash active substances and thus their detergency (synergistic effect).

To an increasing extent, $Na_5P_3O_{10}$ is also used in automatic dishwasher detergents, which contain 20 – 50 % pentasodium triphosphate. In this application, the triphosphate is used especially for its water softening and dispersing properties and for its advantageous pH range [136].

Food Industry. The versatile applicability of condensed phosphates in the production and processing of food is essentially due to their ion-exchange and colloid properties.

In the production of processed cheese, condensed phosphates are used as rectifying or melt salts. In the production process, calcium caseinate is converted by sodium polyphosphates to sodium caseinate and is peptized. A stable suspension is formed from this product together with milk fat, finely dispersed during melting, and the substances dissolved in the aqueous phase. Polyphosphates of medium chain length are preferred for this application. An important application of long-chain polyphosphates is their bacteriostatic effect in cheese products. To a small extent, mono- and diphosphates are added as corrective and buffer salts [95].

Polyphosphates are also used in the production of concentrated milk products such as evaporated milk and milk powder, especially to prevent aggregation of the casein (heat coagulation) by deactivation of calcium ions.

Furthermore, the dispersing and calcium-binding properties of polyphosphates are utilized in the preparation of instant puddings, ice cream, skimmed milk products, and instant sauces. In end-products, they act as stabilizers for batters and as gelation regulators.

Polyphosphates are used for prevention of blood coagulation in the preparation of blood plasma from the blood of slaughtered animals in the Fibrisol process.

Polyphosphates effect disaggregation and peptization of muscular albumin. Thus, they act similarly to natural adenosine triphosphate, which is present in living organisms but not in meat. This effect of polyphosphates, especially of diphosphates, is utilized in the preparation of cooked sausage and boiled, cured meats to avoid loss of quality due to a change in the protein structure and the resulting loss of tissue water.

Baking Aids. Disodium dihydrogendiphosphate is widely used as an acid carrier in baking powders, especially in Europe. At moderate temperatures it does not react with $NaHCO_3$ contained in baking powder and thus permits the preparation or storage of large amounts of dough. The acidic diphosphate reacts with sodium hydrogencarbonate only during the baking process with evolution of carbon dioxide and formation of tasteless disodium monophosphate. In the United States, $Na_2H_2P_2O_7$ is used only for fine baked products; otherwise monocalcium phosphate, $Ca(H_2PO_4)_2 \cdot H_2O$, is used predominantly. Because of its high reactivity towards sodium hydrogencarbonate, monocalcium phosphate is often mixed with sodium aluminum sulfate, $NaAl(SO_4)_2$, which reacts only at baking temperature. In addition, it is added to flour as "bread improver" in bread baking [137].

Sodium aluminum phosphates of composition $NaH_{14}Al_3(PO_4)_8 \cdot 4\ H_2O$ and $Na_3H_{15}Al_2(PO_4)_8$ are now used in the United States as acid carriers in baking powders [137]. They are less reactive than monocalcium phosphate and develop their full effect as expanding agents only at baking heat. This is advantageous especially for the durability of prefinished mixtures.

Leather Industry. In the production of leather, polyphosphates act in various ways. During the soaking of hides and skins, they prevent coagulation of blood and reduce the hardness of the water. In the liming step, the properties of a dispersing agent are necessary. The polyanions stabilize the lime slurry in the state of single solid particles, which are able to penetrate quicker. The result is a short and effective liming step. Another important function is the reaction with protein chains in the skin. It is comparable with a mild tanning process, so polyphosphates are used as pretanning agents [95]. These functions are important in the commonly used tannage with chromium salts and in classical vegetable tannage. In the latter process the iron-binding capacity is also essential, because the complexation of iron ions by polyphosphates prevents the formation of iron stains. During the complete beamhouse work, many washing steps are necessary. Addition of polyphosphates to the water prevents the formation of lime stains or lime shadows by complexing Ca ions.

Paint Industry. In the production of paints, especially emulsion paints, the main components water, pigments, fillers, and binder are stirred together to form a paint with good application properties. Manufacturers aim for high solids contents to give good covering power and for good storage stability of the paint. Both goals can be achieved by adding dispersing agents to the water in the first production step. Polyphosphates are well-known dispersing agents. Comparative tests show that Polyphosphates with chain lengths between $n = 6$ and $n = 10$ give the best results. The dispersing effect is due to adsorption of anionic phosphate molecules on the surface of the pigments and fillers, which eliminates the attractive forces between the particles [196]. In current emulsion paint formulations, a combination of polyphosphates and polyacrylates is used, because in addition to optimal dispersing and storage results advantages in scrubbing resistance can be obtained.

Construction Industry. Short-chain polyphosphates, especially the di- and triphosphates, are used as setting retarders for concrete and cement-based mortar. Addition of combinations of tartraric or citric acid with long-chain polyphosphates to gypsum plaster results in optimum workability and plasticity. In cement-based self-leveling floor compounds, condensed phosphates increase the open time and the fluidity of the formulation.

Ceramics Industry. The production of large quantities of ceramic materials (e.g., tiles) requires very homogeneous raw materials. These so-called ceramic slips are formulations of different clays and additives and are prepared in a wet stage by mixing and grinding the components in ball mills. After homogenization the slips must be dried in spray towers to give granular materials. Normal ceramic slips have a solids content of 55 – 60 %. The energy consumption of the spray drier could be lowered by increasing the solids content. By adding small amounts (0.5 – 1.0 %) of polyphosphates to the slips during the ball mill process, solids contents of 70 % can be attained. The polyphosphate anions are adsorbed on the surface of the silicate particles and act as a deflocculant. Calculations show that the decreased energy demand in the spray drier is economically favorable for the overall process [197].

Other Uses. Polyphosphates are also used as dispersing agents and stabilizers in textile dyeing and printing, as well as in the paper industry for the prevention of resin excretions and for improving coatings and fillers [95]. They are also added to drilling muds in oil well drilling because of their emulsion stabilizing effect [95].

3.3. Other Phosphates

A range of inorganic phosphates, including zinc and chromium phosphates, are used as corrosion-inhibiting pigments; these are discussed elsewhere, ⟶ Metals, Surface Treatment. For phosphating of metal surfaces, see ⟶ Metals, Surface Treatment – Phosphating.

3.3.1. *Potassium Phosphates*

Potassium Monophosphates. Potassium forms the following monophosphates:

KH_2PO_4
$KH_2PO_4 \cdot H_3PO_4$
$KH_2PO_4 \cdot 2\ K_2HPO_4 \cdot H_2O$
$KH_2PO_4 \cdot 3\ K_2HPO_4 \cdot 2\ H_2O$
K_2HPO_4
$K_2HPO_4 \cdot 3\ H_2O$
$K_2HPO_4 \cdot 6\ H_2O$
K_3PO_4
$K_3PO_4 \cdot 3\ H_2O$
$K_3PO_4 \cdot 7\ H_2O$
$K_3PO_4 \cdot 9\ H_2O$

Properties. Generally, the potassium salts are more water soluble than the corresponding sodium monophosphates. Monopotassium dihydrogenphosphate, KH_2PO_4, is an exception; it is substantially less soluble than the other potassium monophosphates and monosodium phosphates. Figure 26 shows the solubilities of the potassium monophosphates.

Figure 26. Solubility of potassium monophosphates [70]

The pH of 1 % aqueous solutions are 4.5 for KH_2PO_4, 9.1 for K_2HPO_4, and 11.8 for K_3PO_4. Like the corresponding rubidium and cesium salts, potassium dihydrogenphosphate forms ferroelectric crystals (T_C of KH_2PO_4, –151 °C). The alkali dihydrogenphosphates (K, Rb, Cs, NH_4) exhibit piezoelectric behavior [70].

Production. Potassium monophosphates are usually produced by the same process as the corresponding sodium salts, i.e., from phosphoric acid and potassium hydroxide. For KH_2PO_4, the cheaper potassium chloride is also used instead of KOH [138]. Various methods have been suggested for quantitative removal of the hydrogen chloride formed: use of ion exchangers [139], long-chain tertiary amines [140], or distillation with octane [141]. The economics depend on the possibility of using the hydrogen chloride.

Uses. The potassium phosphates KH_2PO_4 and K_2HPO_4 are used in the food area for mineral enrichment of fruit juices and as stabilizers in milk products. Potassium dihydrogenphosphate is used as a nutrient salt for mushrooms and cormophytes. Crystals of KH_2PO_4 are used as piezoelectric vibrators [142]. Dipotassium phosphate is suitable as a buffer in the range pH 9, e.g., for pH adjustment of water – glycol mixtures in cooling systems of automotive engines in order to avoid corrosion [143]. Mono- and dipotassium phosphate are further processed to potassium polyphosphates.

Tetrapotassium diphosphate [7320-34-5], tetrapotassium pyrophosphate, $K_4P_2O_7$, M_r 330.35, crystallizes in the anhydrous form and the mono- and trihydrates. The anhydrous salt and the monohydrate are strongly hygroscopic. The solubility of $K_4P_2O_7$ in water is 187 g/100 g H_2O at 25 °C, and the pH of a 1 % aqueous solution is 10.3.

Tetrapotassium diphosphate is produced by the same methods as the corresponding sodium salt, i.e., by dehydration of K_2HPO_4 at 350 – 460 °C. Like the other alkali-metal polyphosphates, $K_4P_2O_7$ also has pronounced dispersive properties as well as the capacity to bind multivalent cations and to keep them in solution. Despite the higher price, tetrapotassium diphosphate is used preferentially as builder in liquid detergent formulations containing 20 – 25 % diphosphate and ca. 50 % water in addition to wash active substances. The reasons are the substantially higher water solubility compared with the sodium salts and the hydrolytic stability of the diphosphate anion.

Potassium diphosphate is also used as a stabilizer in foods and for the prevention of tartar formation. Use as a catalyst in the production of Buna is mentioned in some product information brochures.

Pentapotassium triphosphate [13845-36-8], potassium tripolyphosphate, $K_5P_3O_{10}$, M_r 448.43, *mp* 614.5 °C (decomp.), crystallizes in the anhydrous form and as the dihydrate. The anhydrous salt is strongly hygroscopic. Its solubility in water is ca. 200 g/100 g H_2O at 20 °C. The pH of a 1 % aqueous solution is 11.5. Like the corresponding sodium compound, pentapotassium triphosphate is produced from 2 mol of K_2HPO_4 and 1 mol of KH_2PO_4. It is used as a builder in liquid detergents.

Kurrol's salt [29057-10-1], (high-molecular potassium polyphosphate) $(KPO_3)_x$, M_r $(118.09)_x$, where *x* can vary from 400 to 20 000 depending on the conditions of preparation, *d* 2.26, *mp* 813 °C. Although it is a true polyphosphate with chain structure, the incorrect designation potassium metaphosphate is frequently still found in the literature. Kurrol's salt is insoluble in pure water. However, in the presence of other alkali-metal ions, especially Na^+, it dissolves to form a viscous gel.

Kurrol's salt is generally produced by heating KH_2PO_4 at 350 – 500 °C in a rotary kiln. In another process, $(KPO_3)_x$ is produced as a spray dried product from aqueous KH_2PO_4 solution in a hot gas stream at 330 – 390 °C [144]. Due to its good dispersing action, Kurrol's salt is used as an additive in soaps and cleansing agents.

3.3.2. *Ammonium Phosphates*

The most important application of ammonium phosphates is as fertilizers (⟶ Phosphate Fertilizers). Other applications are known, especially as flame retardants.

The following crystalline monophosphates exist in the $NH_3 – P_2O_5 – H_2O$ system [145]:

$NH_4H_2PO_4$	$(NH_4)_2HPO_4$
$NH_4H_2PO_4 \cdot H_3PO_4$	$(NH_4)_3PO_4 \cdot 3\ H_2O$
$NH_4H_2PO_4 \cdot H_3PO_4 \cdot H_2O$	$(NH_4)_3PO_4 \cdot 2\ (NH_4)_2HPO_4$

Only the mono- and diammonium phosphates are commercially important. The compound $(NH_4)_3PO_4$ and the double salt $(NH_4)_3PO_4 \cdot 2\ (NH_4)_2HPO_4$ are unstable at room temperature. They decompose with release of ammonia and formation of $(NH_4)_2HPO_4$.

Ammonium dihydrogenphosphate [7722-76-1], monoammonium phosphate, $NH_4H_2PO_4$, M_r 115.03, *d* 1.80, tetragonal, *mp* 190 °C; solubility in water, 36 g $NH_4H_2PO_4$/100 g H_2O at 20 °C, and 120 g at 80 °C; pH of a 1 % aqueous solution, 4.5. The crystals have piezoelectric properties. In contrast to the tri- and diammonium salts, monoammonium phosphate is very stable (pNH_3, 7 Pa at 125 °C) and melts at 190 °C without decomposition.

Single crystals of monoammonium phosphates are used, e.g., in underwater sounding equipment instead of quartz oscillators. Moreover, monoammonium phosphate has applications in ceramic binders and for the production of special fertilizers (⟶ Phosphate Fertilizers).

For production, see Diammonium Hydrogenphosphate.

Diammonium hydrogenphosphate [7783-28-0], diammonium phosphate, $(NH_4)_2HPO_4$, M_r 132.07, *d* 1.62, monoclinic, *mp* 155 °C (decomp.); solubility in water, 72 g $(NH_4)_2HPO_4$/100 g H_2O at 25 °C; pH of a 1 % aqueous solution, 8.0; pNH_3, 27 Pa at 50 °C and 1.21 kPa at 100 °C.

Ammonium monophosphates are produced by neutralization of phosphoric acid with ammonia. Crude or partially purified wet phosphoric acid is mostly used for fertilizer applications. However, pure thermal phosphoric acid is used preferentially for the production of commercial ammonium phosphates with an assay > 99 %. Commercial ammonium monophosphates are used for flame-retardant textile finishes (not washfast), as flame-retardant impregnating agents for wood, and as components of fire-extinguishing powders. Matches are impregnated with ammonium phosphate solutions to prevent smoldering. The flame-retardant effect of ammonium phosphates is due to their decomposition to phosphoric acid and ammonia. The generated phosphoric acid catalyzes carbonization of combustible material such as cellulose, so that the formation of readily combustible, gases (e.g., CO) is decreased. A film of condensed phosphoric acids or ultraphosphates is formed, which shields the substrate against heat and protects it from access of atmospheric oxygen [146].

Ammonium polyphosphates, $(NH_4)_{n+2}P_nO_{3n+1}$, cannot be produced from ammonium monophosphates by thermal condensation because the ammonia partial pressure is too high at the required temperatures. Short-chain ammonium polyphosphates are produced by neutralization of polyphosphoric acids with ammonia [147]. They are water soluble and used predominantly as components of liquid fertilizers (⟶ Phosphate Fertilizers).

High-molecular ammonium polyphosphate with a minimum of water-soluble fractions is being used to an increasing extent in flame retardants. Five modifications with a chain length of *n* > 50 are described in the literature [148]. Form I or form II products are produced preferentially for commercial applications. The NH_3 partial pressure of form I is 0.053 kPa at 100 °C, 3.19 kPa at 200 °C, and 49.5 kPa at 300 °C [148]. In order to carry out the reaction at low temperatures, urea or similar compounds such as melamine are used as ammonia sources [148], [149].

$$x\,H_3PO_4 + x\,CO(NH_2)_2 \rightarrow (NH_4PO_3)_x + x\,CO_2 + x\,NH_3$$

In another process, phosphorus pentoxide is reacted with diammonium phosphate and ammonia in a mixing and kneading machine [150].

$$x/2\,P_4O_{10} + x(NH_4)_2HPO_4 + x\,NH_3 \rightarrow 3(NH_4PO_3)_x$$

The phosphorus pentoxide/diammonium phosphate/urea combination is also suitable for the production of high-molecular products [151].

$$x/2\,P_4O_{10} + x(NH_4)_2HPO_4 + x/2\,CO(NH_2)_2 + x/2\,H_2O \rightarrow 3(NH_4PO_3)_x + x/2\,CO_2$$

In this reaction, some product properties can already be influenced by the choice of starting materials. An ammonium polyphosphate with a high proportion of modification I and chain lengths of *n* = 40 to *n* = 200 is formed predominantly if urea is used as ammonia source. However, if gaseous ammonia is used, a modification II product with chain lengths of *n* >1000 is obtained. The reasons for these reaction characteristics are related to the reaction rate. If urea is used, then ammonia supply is optimal provided that the components are thoroughly mixed. Accordingly, the reaction proceeds very quickly, and the kinetically favored product is formed. Thermodynamically stable ammonium polyphosphate of modification II is formed only if the reaction proceeds slowly such as in a kneading machine and at temperatures of 240 – 290 °C.

All manufacturing processes have to be carried out in an ammonia atmosphere so that the NH_3 partial pressure exceeds the decomposition pressure of ammonium polyphosphate.

Long-chain ammonium polyphosphates are used as fire-extinguishing agents [152], as flame retardants for paints and varnishes, for flame-retardant finishing of polyurethane foams [153], and in fireproof coatings on steel beams and wooden partitions [154].

3.3.3. *Magnesium Phosphates*

With the exception of magnesium-containing mixed phosphates used in feeds, magnesium phosphates have only minor commercial significance.

Magnesium dihydrogenphosphate [13092-66-5], monomagnesium phosphate, $Mg(H_2PO_4)_2$, M_r 218.28, crystallizes in the anhydrous form and as the di- and tetrahydrate. On dissolution in water, partial hydrolysis occurs with formation of monophosphoric acid and crystalline magnesium hydrogenphosphate, $MgHPO_4 \cdot 3\ H_2O$. Acidic magnesium diphosphate is formed on heating to above 170 °C. It condenses at higher temperatures to give higher-molecular polyphosphates. The hydrated salts are obtained by dissolution of magnesium oxide, magnesium carbonate, or di- or trimagnesium phosphate in phosphoric acid and subsequent crystallization. The anhydrous compound is formed by dehydration at 100 – 170 °C.

Magnesium hydrogenphosphate, dimagnesium phosphate, $MgHPO_4$, M_r 120.29. Only the trihydrate, $MgHPO_4 \cdot 3\ H_2O$, *d* 2.12, orthorombic, *mp* 205 °C (with loss of H_2O), is stable at 25 °C in the $MgO – H_2O – P_2O_5$ system. It is also the usual commercial product. In addition, the anhydrous salt and the mono- and heptahydrate are described in the literature. The trihydrate occurs as the natural mineral newberyite. It dissolves in dilute acids but is practically insoluble in water. It is produced by double decomposition of disodium phosphate with magnesium salts in aqueous solution or by neutralization of solutions of magnesium salts in phosphoric acid with caustic soda.

Magnesium hydrogenphosphate is used for mineral enhancement in foods for babies and athletes as well as in dietetic foods. It is also utilized as a feedstuff additive, in the ceramic industry, and as a stabilizer for $CaHPO_4 \cdot 2\ H_2O$ in toothpastes [155].

Trimagnesium phosphate [7757-87-1], $Mg_3(PO_4)_2$, M_r 262.88, *mp* 1184 °C, crystallizes with 5, 8, and 22 H_2O. The octahydrate, *d* 2.19, monoclinic, occurs as the mineral bobbierite. $Mg_3(PO_4)_2 \cdot 22\ H_2O$, *d* 1.66, also crystallizes in the monoclinic form. The salts are practically insoluble in water but readily soluble in acids. The anhydrous salt is

formed by heating the hydrates at 400 °C. Hydrated trimagnesium phosphate can be prepared from solutions of magnesium salts by addition of trisodium phosphate solution or phosphoric acid and caustic soda. It is used as anticaking agent for silicate-containing cleaning agents [156] and table salt and as a stabilizer for $CaHPO_4 \cdot 2\ H_2O$.

3.3.4. *Calcium Phosphates*

For production and use of calcium phosphates in fertilizers see ⟶ Phosphate Fertilizers. Pure calcium phosphates are used predominantly as feedstuff additives and as polishing compounds in toothpastes.

Calcium dihydrogenphosphate, monocalcium phosphate, $Ca(H_2PO_4)_2 \cdot H_2O$, M_r 252.09, *d* 2.22, triclinic, loses its water of crystallization starting at 109 °C, with formation of anhydrous $Ca(H_2PO_4)_2$ [7758-23-8], *d* 2.55, triclinic.

Monocalcium phosphate dissolves in water with precipitation of calcium hydrogenphosphate and formation of an aqueous phase with increased P_2O_5 content:

$$Ca(H_2PO_4)_2 \cdot H_2O \rightleftharpoons CaHPO_4 + H_3PO_4 + H_2O$$

Therefore, preparation of pure $Ca(H_2PO_4)_2 \cdot H_2O$ [10031-30-8] by crystallization from aqueous solution succeeds only in the presence of excess phosphoric acid [157]. Adhering phosphoric acid gives hygroscopic products which tend to decompose further by absorption of atmospheric moisture. Therefore, commercial products are made with an excess of CaO and contain up to 20 % calcium hydrogenphosphate.

Monocalcium phosphate is produced by neutralization of phosphoric acid with calcium oxide or hydroxide [158]. Only thermal phosphoric acid is used for production of food-grade quality (e.g., for baking aids). Defluorinated wet phosphoric acid is used mostly for feed phosphate. The starting materials are reacted in vessels made of stainless steel by means of high-intensity agitators or in continuously operating mixers. Some of the water is evaporated by the heat of reaction. A pulpy to crumbly product is obtained, which is subsequently dried and ground.

Products with low bulk density are obtained from a slurry of the starting components by spray drying with hot air. Predominantly monohydrate is produced by these processes because the anhydrous salt is less stable towards atmospheric moisture.

A relatively water-stable, less reactive product is obtained by addition of small amounts of various metal salts, e.g., of potassium or aluminum [132].

The anhydrous salt is formed by carrying out the reaction at 140 °C. In a posttreatment step at 200 – 220 °C, the crystals become coated with a glassy, essentially water-stable, protective layer (anhydrous coated calcium phosphate, ACCP).

In the United States, monocalcium phosphate is used mainly as a leavening aid in the production of self-raising flour. Further applications are in mineral enrichment of foods, as a stabilizer for milk products, and as a feedstuff additive in place of calcium hydrogenphosphate.

Calcium hydrogenphosphate [7757-93-9], dicalcium phosphate, $CaHPO_4$, M_r 136.06, crystallizes in the anhydrous form, *d* 2.89, triclinic, and as the dihydrate, *d* 2.32, monoclinic. The dihydrate is slowly converted to the anhydrous salt at 36 °C (incongruent melting point). Substantially higher temperatures are required for production of the anhydrous salt. $CaHPO_4 \cdot 2\ H_2O$ dissolves in water with precipitation of hydroxyapatite, $Ca_5(PO_4)_3OH$, and formation of an aqueous phase with increased P_2O_5 content. However, its solubility is low (220 mg/L CaO and 530 mg/L P_2O_5 at 25 °C).

The dihydrate is produced by neutralization of phosphoric acid with calcium hydroxide, with cooling to avoid formation of anhydrous $CaHPO_4$. Thermal phosphoric acid is used as starting material in the production of $CaHPO_4 \cdot 2\ H_2O$ for use in toothpastes. However, feedstuff phosphates are produced predominantly from defluorinated wet phosphoric acid.

For defluorination, the acid is partially neutralized with calcium hydroxide or carbonate. The fluoride precipitates as calcium hexafluorosilicate together with phosphates of bi- or multivalent metal ions such as Fe and Al. The P_2O_5-containing precipitate is filtered and used for fertilizer production. Na_2SiF_6 or K_2SiF_6 can also be precipitated by addition of sodium or potassium salts. After subsequent addition of calcium hydroxide, the precipitated $CaHPO_4 \cdot 2\ H_2O$ is filtered, dried, and ground.

For a large decrease of the fluoride content, an additional defluorination can be carried out by adding SiO_2 in the form of bentonite [159].

In a more recent process, stoichiometric quantities of $CaCl_2$, NaOH, and H_3PO_4 are added simultaneously to an intensively agitated reactor [160]. In a variation of this process, $CaCl_2$ and NaOH are partially replaced by an aqueous suspension of calcium carbonate [161].

The water-adsorptive capacity of $CaHPO_4 \cdot 2\ H_2O$ also has a function in its application as a polishing compound in toothpastes. Highly adsorptive products can be prepared by adding H_3PO_4 to a suspension of $CaCO_3$ and homogenizing the reaction mixture at the drip spot with a disperser [162].

The anhydrous salt is produced by the same processes as are used for the dihydrate, but precipitation is carried out above 80 °C. Calcium hydrogenphosphate, in the form of its dihydrate and sometimes also as anhydrous salt, is used as a mineral supplement in feedstuff. The dihydrate is used as a component of toothpastes because of its advantageous polishing properties and low abrasiveness [163]. Stabilizers such as $MgCl_2$, $Mg_3(PO_4)_2$, $MgHPO_4 \cdot 2\ H_2O$, or $Na_4P_2O_7$ are added to prevent hardening of toothpastes prepared with $CaHPO_4$ due to dehydration during storage.

Calcium hydrogenphosphate is used in the food industry for mineral enrichment of various products, and in the pharmaceutical industry as a pelletizing aid and thickening agent. Use as fertilizer component for tropical soils is a special application of $CaHPO_4$.

Tricalcium phosphate [7758-87-4], $Ca_3(PO_4)_2$, M_r 310.20, *d* 3.14 (whitlockite, rhombohedral); solubility in water 2.5 mg $Ca_3(PO_4)_2$/100 g H_2O at 25 °C. Two crystalline modifications are known, the high-temperature α- and the low-temperature β-form, transition temperature 1180 °C, *mp* 1730 °C. In production, hydroxyapatite, $Ca_5(PO_4)_3OH$, is formed by complete neutralization of phosphoric acid with slaked lime and subsequent filtration, drying, and grinding. The Ca/P ratio depends on the process conditions. Pure $Ca_3(PO_4)_2$ with a Ca/P ratio of 1.5 can be obtained from hydroxyapatite by calcination above 900 °C. However, commercial tricalcium phosphate consists mostly of hydroxyapatite.

Tricalcium phosphate is added to various substances such as table salt, sugar, and fertilizers as anticaking agent in amounts of 1 – 2 %. It is used in toothpastes containing calcium hydrogenphosphate for adjustment of the polishing strength.

Tricalcium phosphate and calcium halophosphates such as $Ca_5(PO_4)_3(F,Cl)$ are used in the manufacture of luminescent materials.

Dicalcium diphosphate [7790-76-3], calcium pyrophosphate, $Ca_2P_2O_7$, M_r 254.11, *d* 3.09, orthorhombic, *mp* 1353 °C, is practically insoluble in water but soluble in acids. It is produced by thermal dehydration of $CaHPO_4$ or $CaHPO_4 \cdot 2\ H_2O$ at 700 – 900 °C. Dicalcium diphosphate is used as a polishing compound in fluoridated toothpastes because of its low solubility and its inertness towards fluoride ions [164].

Calcium triphosphate [26158-70-3], calcium tripolyphosphate, $Ca_5(P_3O_{10})_2$, M_r 706.47, is practically insoluble in water. It is produced as the octahydrate from calcium chloride solutions by precipitation with pentasodium triphosphate. It is added to hygroscopic salts such as table salt for preservation of the pourability and as a stabilizer for $CaHPO_4 \cdot 2\ H_2O$ [165].

3.3.5. *Boron Phosphate*

Boron phosphate [13308-51-5], BPO_4, M_r 105.79, *d* 2.80, tetragonal, is a white, crystalline solid that sublimes at 1450 °C without decomposition. In addition to the anhydrous product, hydrates with 3, 4, and 6 H_2O have also been reported. The hydrates dissolve readily in water with hydrolysis to give the corresponding acids. The anhydrous salt also hydrolyzes but at a much slower rate. Under ambient conditions, BPO_4 has a cristobalite structure consisting of alternating BO_4 and PO_4 tetrahedra linked via common oxygen atoms to form a three-dimensional network.

Boron phosphate is produced by reaction of boric acid with 85 % phosphoric acid and subsequent dehydration at up to 1000 °C [166]. A product with very large specific surface area is obtained by heating tri-*n*-propyl borate with phosphoric acid at 120 – 130 °C [167]. Addition of aluminum hydroxide in combination with ethylenediamine and ethyl acetate or of the combination aluminum oxide chloride/urea has the same effect [168].

Boron phosphate is used in organic chemistry as a catalyst in various syntheses, especially in hydration, dehydration, isomerization, and amination reactions [169], and in the

ceramic industry as a carrier for boric acid and phosphate.

3.3.6. *Aluminum Phosphates*

The following aluminum monophosphates are known in the Al_2O_3 – P_2O_5 – H_2O system: $Al(H_2PO_4)_3 \cdot n\ H_2O$, $Al_2(HPO_4)_3 \cdot n\ H_2O$, and $AlPO_4 \cdot n\ H_2O$. Acidic salts of composition $Al(H_2PO_4) \cdot (HPO_4) \cdot n\ H_2O$ are also known.

Aluminum dihydrogenphosphate [13530-50-2], monoaluminum phosphate, $Al(H_2PO_4)_3$, M_r 317.96, water soluble, exists in the anhydrous form (hexagonal) and as the trihydrate. On heating to 250 °C, acidic aluminum triphosphate ($AlH_2P_3O_{10}$) is formed, which condenses above 500 °C to give long-chain polyphosphate and cyclic tetrametaphosphate. The trihydrate is obtained by reaction of aluminum hydroxide with phosphoric acid and subsequent crystallization. It is used as binder for highly fireproof materials [170].

Aluminum phosphate [7784-30-7], $AlPO_4$, M_r 121.95, *d* 2.57, *mp* 1850 ± 50 °C, crystallizes in the anhydrous form as hexagonal berlinite. Cubic and orthorhombic modifications are also known. It also crystallizes as a dihydrate (variscite, orthorombic); a monoclinic modification also exists. It is practically insoluble in water and sparingly soluble in acids. It dissolves in alkalies with formation of aluminates. $AlPO_4$ is isotypic with SiO_2 and forms polymorphous modifications with quartz, tridymite, and cristobalite structures.

Aluminum phosphate is produced by addition of alkali-metal phosphates to solutions of aluminum salts or by treating sodium aluminate solution with phosphoric acid.

It is used in the manufacture of molecular sieves and optical glasses, in ceramics, in the enamel industry, and as an anticorrosion powder in coatings.

Aluminum polyphosphate, $[Al(PO_3)_3]_n$, is insoluble in water and acids. Upon heating at 900 – 1000 °C it is converted to a cyclic tetrametaphosphate with *mp* 1230 –1250 °C [171]. Aluminum polyphosphate is produced from monoaluminum phosphate by heating at 600 °C. It is used in the enamel industry in heat-resistant glasses and as component of optical glasses. Aluminum polyphosphates with a molar ratio P_2O_5:Al_2O_3 of ca. 2.5 can be used as hardeners for water glass putties [172].

3.4. Economic Aspects

Tables 8, 9, 10, 11, and 12 list regional and world demand for phosphates in various applications. The following abbreviations are used:

MSP. monosodium phosphate
DSP. disodium phosphate
TSP. trisodium phosphate
TSPP. tetrasodium pyrophosphate
TKPP. tetrapotassium pyrophosphate
STPP. sodium tri(poly)phosphate
SHMP. sodium hexametaphosphate
MCP. monocalcium phosphate
DCP. dicalcium phosphate
DAP. diammonium phosphate
TCP. tricalcium phosphate
SAPP. acidic sodium pyrophosphate
SAlP. sodium aluminum phosphate
IMP. Maddrell's salt (insoluble)
SMFP. sodium monofluorophosphate
APP. ammonium polyphosphate
ZnP. zinc phosphates
AlP. aluminum phosphates

4. Toxicology

Thomas Hofmann

Phosphoric Acid. Analogous to phosphorus pentoxide, phosphoric acid does not possess any specific toxic effects. Phosphoric acid irritates the eyes, respiratory tract, and mucous membranes. Aqueous solutions containing phosphoric acid in concentrations > 10% are irritating, solutions with concentrations > 25% are corrosive. After swallowing larger quantities, nausea, vomiting, diarrhea, hematemesis, and hypovolemic shock occur. Ingestion of concentrated solutions causes burns of the mucosa of the mouth, esophagus, and stomach. Additionally, hyperphosphatemia, hypocalcemia and acidosis may be present [173], [174]. Washing of the skin with warm water, irrigation of the eyes with warm water or physiological saline solution is recommended in case of contamination. First aid after ingestion consists of support of respiration and treatment of shock by intravenous replacement of lost fluid volume [174]. The systemic toxicity of phosphoric acid is low. No effect on growth and reproduction was observed in three generations of rats that received 0.75% phosphoric acid in the diet for 90 weeks. No pathological findings attributable to the administration of phosphoric acid were observed in this study. Dental attrition was somewhat higher than in controls [175]. Phosphoric acid was not mutagenic in the Ames test [176]. Phosphoric acid can be used in concentrations of 500 – 1000 mg/L in beverages. No changes which could indicate any detrimental effect on metabolism could be established in voluntary subjects who took 2000 – 4000 mg/kg per day orally for 10 d or 3900 mg/kg per day for 14 d [177]. The TLV-TWA value for phosphoric acid is 1 mg/m^3 [178].

Phosphates and Polyphosphates. A summary of the toxicological properties of phosphates and polyphosphates is given in [179], [180]. There was no evidence for genotoxicity of inorganic phosphates in various test systems. Embryo-fetal toxicity studies in rats, mice, rabbits, and hamsters did not reveal any evidence of teratogenicity. The toxicological profiles phosphates and polyphosphates are largely similar, provided no toxic cations are present. Hyperphosphatemia, secondary hyperparathyreoidism, skeletal changes (deformations, bone loss), and calcification were observed in animal studies after administration of high phosphate dosages. In subchronic and chronic feeding studies with rats, primarily nephrocalcinosis occurred, whereby this species is particularly sensitive to acids that form calcium chelates or complexes. The effective dosages overlap in the different studies; the lowest concentration which caused nephrocalcinosis was 10 g per kg of feed. In view of these results, it was concluded that the oral intake of 70 mg of phosphate (as phosphorus) per kilogram of body weight per day is tolerable in humans (70 mg is the MTDI, maximum tolerable daily intake) [180].

Hypocalcemia, hyperphosphatemia, and dehydration have been reported in studies where sodium phosphate/biphosphate was administered as an enema [181]. Sodium hexametaphosphate, which is used for softening water, can cause serious, or even fatal poisoning when taken orally. The most prominent symptoms are massive shock, irregular pulse, eventually bradycardia, and severe hypocalcemia with tetanic symptoms. Lavaging the stomach with chalk and repeated intravenous injection of calcium gluconate are recommended as therapy [182].

Chlorinated trisodium phosphate, which is used in various cleaning compounds, has a low acute and subchronic toxicity in rats and mice. Toxic effects after chronic administration were observed in rats and were attributable to local irritation/corrosion, which led to termination of the two-year carcinogenicity bioassay. The compound was not carcinogenic after administration for two years to mice. Like sodium hypochlorite, it is a weak base-pair substitution mutagen in bacteria [183].

Sodium monofluorophosphate is used in dentifrices [184] and for treatment of osteoporosis in postmenopausal women [185]. Toxic effects after administration of higher doses (fluorosis) are related to fluoride [186].

1. Introduction

Phosphorus, P [*7723-14-0*], atomic number 15, A_r 30.98, is a member of group 15 of the Periodic Table. In its compounds, phosphorus exhibits oxidation numbers between −3 and +5.

Phosphorus occurs in three main allotropic forms: white (yellow when slightly impure) [*7723-14-0*], red, and black. Other forms of solid phosphorus are derived from these three main allotropes. Only white and red phosphorus are of industrial importance.

The only stable isotope of phosphorus is ^{31}P. Of the seven known unstable isotopes of phosphorus, only ^{32}P and ^{33}P, with half-lifes of 12.26 d and 25.3 d, respectively, are suitable for isotopic labelling [1].

History. White phosphorus was first prepared by HENNIG BRAND in 1667 by evaporating urine and strongly heating the residue in the absence of air. Soon afterwards, phosphorus received its name (light bearer). In 1715, GMELIN published a method of preparation based on the reaction of the residue from the evaporation of urine with charcoal and sand. The sodium metaphosphate formed ($NaPO_3$) reacted with the carbon to form white phosphorus.

In the 1800s, PELLETIER, further developed a process invented by SCHEELE for the production of white phosphorus for matches. Bone ash was first reacted with sulfuric acid to produce $Ca(H_2PO_4)_2$ [*7758-23-8*], which was then reacted at high temperatures with wood charcoal to form white phosphorus, $Ca_3(PO_4)_2$ [*7758-87-4*], and CO. Only two-thirds of the phosphorus in the $Ca(H_2PO_4)_2$ was recovered as white phosphorus.

In the mid-1800s, Albright & Wilson started the production of white phosphorus in England. Syrupy phosphoric acid was reacted with wood charcoal in clay retorts, and the phosphorus was distilled off. The development of the electric furnace at the end of the century enabled a method of manufacture originally invented by WO in 1829 to be developed into an industrial process. Tricalcium phosphate, coke, and silica were reacted to produce white phosphorus, calcium metasilicate [*10101-39-0*], and carbon monoxide:

$$2\,Ca_3(PO_4)_2 + 6\,SiO_2 + 10\,C \longrightarrow P_4 + 6\,CaSiO_3 + 10\,CO$$

This process, including the use of an electric furnace, was patented by the Englishman READ-

MAN. A single-phase furnace of 80 kW was constructed in England in 1893, and soon phosphorus was being produced in tonnage quantities in electric furnaces in the United States, France, and Germany.

Figure 1. Solubility of white phosphorus

Although white phosphorus was prohibited in matches in the early 1900s because of its toxicity, consumption continued to increase (see Chap. 7).

In 1925 the first three-phase electric furnace (3 MW) was built in Bitterfeld, Germany. In 1927, four 10 MW furnaces were built in Piesteritz, and similar large furnaces were built in the United States in the 1930s.

After World War II, phosphorus production worldwide grew very rapidly. Many phosphorus furnaces with power consumptions of up to 70 MW per furnace were built in the United States, Canada, the Netherlands, the Federal Republic of Germany, the former Soviet Union, and China.

2. Properties

2.1. Physical Properties

Of the three main allotropic forms, only black phosphorus is thermodynamically stable at room temperature; white and red phosphorus are metastable under normal conditions.

White phosphorus is the most reactive of the solid modifications. It is formed on condensation of phosphorus vapor under water as the α-or high-temperature form (cubic) – a transparent, waxy mass with a density of 1.82 g/cm^3. Below −76.9 °C, phosphorus changes into the hexagonal β-form (ϱ 1.88 g/cm^3). Both these forms and the liquid and gaseous phases consist of tetrahedral P_4 molecules.

White phosphorus, *mp* 44.1 °C, *bp* 280.5 °C, is a nonconductor. It is soluble in many liquids, especially in phosphorus trichloride, phosphorus tribromide, and carbon disulfide, and also in organic solvents such as benzene and diethyl ether (see Fig. 1). Further physical data and constants for white phosphorus are given in [2].

Red Phosphorus. The general term red phosphorus includes numerous crystalline or amorphous forms with varying depths of color. The densities are in the range 2.0 – 2.4 g/cm^3 and the melting points between 585 and 610 °C. All the forms of red phosphorus appear to be made up of P_4 molecules polymerized in varying degrees. Above 200 °C, yellow phosphorus changes into red phophorus, the transformation being catalyzed, among others, by water vapor, iodine, and sulfur. Ultraviolet light also accelerates the process. Unlike white phosphorus, red phosphorus has low solubility, is not spontaneously flammable, and is nontoxic.

Commerical red phosphorus is X-ray amorphous and has a density of ca. 2.16 g/cm^3.

Violet or Hittorf's phosphorus is the best defined form of red phosphorus. It was prepared by HITTORF in 1865 by heating phosphorus in contact with molten lead, and by SCHENCK in 1905 from a phosphorus–bismuth melt. The crystal structure of violet phosphorus is rhombohedral or triclinic; the density is 2.34 g/cm^3.

Light red phosphorus, described by SCHENCK, is not a definite modification, but a very finely divided form of red phosphorus. A 10 % solution of white phosphorus in phosphorus tribromide is boiled for 10 h, yielding a product which still contains some solvent. It can be obtained in a pure state by reduction of phosphorus tribromide with mercury. Schenck's phosphorus is appreciably more reactive than the product obtained by the transformation of white phosphorus; for example, it reacts vigorously with alkali , forming phosphine, hydrogen, and hypophosphite.

Other Phosphorus Modifications. The relationships between the known phosphorus modifications are given in [3].

Black phosphorus exists in three crystalline and one amorphous form. All these are highly polymerized, insoluble, and practically nonflammable. BRIDGMAN prepared orthorhombic black phosphorus (ϱ 2.69 g/cm^3) by heating white phosphorus to 200 °C at 12 kbar [4]. Further increase of the pressure leads to reversible formation of the even denser rhombohedral and cubic forms [5]. Orthorhombic black phosphorus can also be prepared at slightly elevated pressures if white phosphorus is heated to 380 °C with mercury and crystal nucleii of black phosphorus [6]. The orthorhombic form can be prepared from a solution of phosphorus in bismuth [7].

Amorphous black phosphorus (ϱ 2.25 g/cm^3) has a partly crystalline structure, but becomes crystalline at higher pressure and temperature.

Brown phosphorus [8] is formed by the condensation of phosphorus vapor containing P_2 molecules (> 1000 °C) onto a surface cooled by liquid nitrogen. Above 0 °C, brown phosphorus changes into a mixture of the white and red forms.

Vitreous, gray phosphorus can be obtained as an intermediate product in the preparation of orthorhombic black phosphorus. It is a dark gray, brittle substance that exhibits conchoidal fracture. It can be ignited by impact and is a nonconductor.

Liquid and Gaseous Phosphorus. The liquid phase consists of P_4 molecules, and is the same irrespective of how it was formed, e.g., by melting of some form of solid phosphorus or by condensation of phosphorus vapor. The density of liquid phosphorus at 50 °C is 1.74 g/cm^3, and its boiling point is 280.5 °C. The vapor pressure curve of liquid phosphorus is shown in Figure 2. In the region of the broken line (between 350 and 510 °C), liquid phosphorus does not exist due to its transformation into red phosphorus. Liquid phosphorus can be supercooled to below − 71.3 °C. Its critical point (triple point) is at 695 °C and 83.3 bar.

Figure 2. Vapor pressure curve of phosphorus

Above 800 °C, the P_4 molecules in the gas phase begin to dissociate, there being equal numbers of P_4 and P_2 molecules at ca. 1200 °C. The extent of dissociation into atomic phosphorus in the vapor is so low that at 1500 °C the concentration of P atoms is < 0.1 %.

2.2. Chemical Properties

White phosphorus burns to form P_2O_5 or the lower oxides such as P_2O_3 and PO_2, depending on the amount of oxygen present. Finely divided white phosphorus is extremely reactive and ignites spontaneously at room temperature in air. In bulk form it burns at ca. 60 °C.

The glow of phosphorus in air can be observed in the dark. The chemical energy of the slow oxidation is converted not only into heat, but also partly into light (chemiluminescence). The Mitscherlich reaction for the determination of small amounts of white phosporus is based on this light emission.

White phosphorus does not react with water under normal conditions, but phosphorus vapor is oxidized by water vapor to form hydrogen and phosphorus pentoxide.

White phosphorus acts as a strong reducing agent towards concentrated oxidizing acids. Sulfuric acid is reduced to sulfur dioxide, and nitric acid to oxides of nitrogen.

The compounds formed by the reaction of phosphorus with halogens or sulfur are described in [9] (see also → Phosphorus Compounds, Inorganic). Carbon monoxide does not react with phosphorus or its oxides, but carbon dioxide has an oxidizing action above 650 °C.

With alkali , white phosphorus undergoes disproportionation to form phosphine and hypophosphite. Phosphorus combines with many metals, e.g., aluminum, zinc, cadmium, iron, and copper, to form well-defined phosphides (→ Phosphorus Compounds, Inorganic). Aqueous solutions of easily reducible metal salts react with white phosphorus on gentle heating, and the metals are precipitated either as such (e.g., gold, silver, lead) or as the phosphides (e.g. Cu_3P_2).

Red phosphorus ignites in air at ca. 300 °C. At room temperature, friction or impact are sufficient for ignition.

3. Occurrence of Phosphates in Nature

Phosphorus does not occur naturally in the free state. It is almost always found in its highest oxidation state (+5) in the form of orthophosphates. These are very widespread: in the earth, in rocks, on the ocean floor, and in the bones of animals. Of the many phosphate minerals, virtually the only one used in industry as a source of phosphorus is apatite. The deposits of aluminum phosphates in Africa and Brazil are of minor industrial importance. Guano is nearly all used in fertilizers.

The following apatites represent the most important raw materials for thermal phosphorus manufacture (in an electric furnace) and for wet dissolution (phosphoric acid production by reaction of phosphate rock with sulfuric acid; → Phosphoric Acid and Phosphates): fluorapatite $Ca_5(PO_4)_3F$ [*1306-05-4*], hydroxyapatite $Ca_5(PO_4)_3OH$ [*1306-06-5*], and carbonatoapatite $Ca_{10}(PO_4)_6(CO_3) \cdot H_2O$ [*12415-02-0*]. They are of either magmatic or sedimentary origin.

The *sedimentary apatites* represent by far the largest quantity of phosphate rock both as regards size of the reserves and amount extracted. Because they mainly originate from animal remains from earlier geological epochs, they also contain sand, silicates, carbonates, and even organic compounds.

In the United States, sedimentary phosphate deposits are spread across the entire country. The phosphate rock is extracted in opencast mines, clay and sand are removed as sludge, and flotation then gives products which are sorted and stored according to their percentage of tricalcium orthophosphate (% BPL: bone phosphate of lime, or % TPL: triphosphate of lime), which is calculated from the P_2O_5 content. The usual industrial grades of phosphate rock in the United States have BPL values of 62 – 75 %.

The phosphate rock is sometimes calcined to decompose the organic compounds, and this to some extent also removes combined CO_2 from the carbonatoapatite and calcite. Calcination also renders the phosphate rock less reactive towards mineral acids.

Morocco is the world's largest exporter of phosphate rock. The sedimentary phosphates in the three deposits Khouribga, Youssuffia, and Bu-Craa (extraction by subsurface mining) vary in the amount of metallic impurities and chloride. The BPL content of the phosphate rock after treatment is 68 – 78 %.

In addition to these two most important producer nations, there are other countries with similar types of deposit, including several Mediterranean countries, the former Soviet Union and China (these two countries being nonexporters), other African countries, and Brazil. However, with the exception of the former Soviet Union and China, these are not of great economic significance.

Magmatic apatites are extracted in only two countries: in the former Soviet Union as Kola phosphate and in South Africa as Phalaborwa

phosphate. Both these ores must be separated from other minerals by flotation. The BPL value for Phalaborwa phosphate is 80 – 88 %, and, for Kola phosphate, 86 %. These phosphates do not contain organic components.

Figure 3. Phosphate output 1900 – 1988 (10^6 t/a)

Table 1 lists typical analytical figures for the important phosphate rocks. All these can in principle be used in electrothermal phosphorus production. The P_2O_5 content should not be too low, as a high content of mineral impurities leads to increased electric power consumption. Metallic impurities can have a detrimental effect on the reaction process. Small amounts of such impurities (e.g., zinc) present in the phosphate rock can build up during the recycling of dusts, etc.

For the wet dissolution process, magmatic phosphate rocks are preferred because of the absence of organic impurities. Depending on the dissolution process, Kola phosphate and Phalaborwa phosphate may differ with respect to ease of filtration of the gypsum.

Economic Aspects. The annual output of phosphate rock increased slowly but steadily from 1900 until the 1940s, and then rapidly from ca. 10×10^6 t at that time to 40×10^6 t in 1960. From 1960 to 1977 the annual output increased to 116×10^6 t. From 1977 to 1988 there was again a rapid increase to ca. 165×10^6 t (see Fig. 3). It is estimated that the natural reserves of phosphate exceed the annual consumption by a factor of 1000.

The United States is still the world's largest producer of phosphate rock, but its share of total world production has decreased. In 1959 it was 44 %, in 1977 ca. 41 %, and in 1988 ca. 28 %. The share held by the former Soviet Union has continually increased: in 1959 it was ca. 16 %, in 1977 ca. 21 %, and in 1988 ca. 24 %. Morocco maintains a constant share: in 1977 it was ca. 15 %, and the same in 1988. China has a 9 % share, and so has become one of the important producing nations. Twelve other nations produced over 10^6 t phosphate rock each in 1988 (see Table 2).

The amount of phosphate rock used in electrothermal production of elemental phosphorus in 1988 has decreased. In 1959, ca. 11 % was used, in 1977 ca. 6 %, and in 1988 ca. 4 %. The reason is the increasing use for fertilizers. In 1988, ca 95 % of the phosphate rock produced was reacted with mineral acids, and of this ca. 95 % was used in fertilizers. The difference of ca. 5 % was used to produce orthophosphoric acid, which was purified and then used in applications where phosphoric acid manufactured by combustion of elemental phosphorus was previously used.

4. Production of White Phosphorus

Large-scale production of white phosphorus uses exclusively the Wöhler process, in which apatites (nearly always fluorapatite) are reacted with coke and silica (flint pebbles or gravel) in low shaft electric furnaces at 1400 – 1500 °C. The reaction proceeds according to the equation

Table 1. Composition of phosphate rocks from various sources (wt % based on dry material)

Type of phosphate rock	P_2O_5	CaO	F	SiO_2	Al_2O_3	Fe_2O_3	CO_2	SO_3
Kola concentrate (USSR)	39.1	51.5	3.4	2.0	1.2	0.7	0.0	0.0

$$4\,Ca_5(PO_4)_3F+18\,SiO_2+30\,C \longrightarrow 3\,P_4+30\,CO+18\,CaSiO_3+2\,CaF_2$$

Experimental production of phosphorus in blast furnaces was carried out in the United States before World War II. Phosphate–carbon briquettes were reacted with silica and coke in the presence of preheated air such that the carbon was oxidized only as far as CO. The phosphorus formed was either condensed or immediately oxidized to P_4O_{10} [11].

Table 2. Phosphate rock production in 1988 [10]

Country [a]	Production, 10^3 t	Average P_2O_5 content, wt %

[a] Countries producing $> 10^6$ t.

The simultaneous production of phosphorus and calcium carbide was also investigated. The reaction is

$$2\,Ca_3(PO_4)_2+28\,C \longrightarrow P_4+16\,CO+6\,CaC_2$$

However, this process did not become industrially established [12].

Reaction Mechanism. sPhosphate and quartzite form a melt in the furnace at the reaction temperature of 1400 – 1500 °C, and the carbon reacts with the ionic phosphate–silicate–fluoride melt according to

$$2\,PO_4^{3-}+Si_6O_{15}^{6-}+5\,C \longrightarrow P_2+5\,CO+2\,Si_3O_9^{6-}$$

The phosphate ion is reduced to gaseous P_2, transferring its charge to the polymeric silicate ions, whose degree of polymerization is thereby reduced.

It is not certain whether this is a solid–liquid reaction [13], or whether CO acts as a reducing agent and the CO_2 formed reacts with carbon to form more CO. It is known that the solid components apatite, silica, and carbon react at 1100 °C to form phosphorus [14]:

$$Ca_3(PO_4)_2+5\,CO \longrightarrow 3\,CaO+5\,CO_2+P_2$$

$$5\,CO_2+5\,C \longrightarrow 10\,CO$$

4.1. Raw Materials

Trouble-free operation of a phosphorus furnace requires that the three raw materials–sintered phosphate, coke, and silica–should have the same grain size distribution, so that the solid burden in the furnace has virtually constant gas permeability throughout its volume. The reaction gases, phosphorus and CO, formed in the lower part of the furnace, should give up as much of their heat as possible to the burden as they pass through the burden bed (see Section 4.2), and this movement of gases should be accompanied by as few pressure fluctuations as possible. A

high dust content in the burden leads to blockages in the burden bed and consequent pressure surges and temperature peaks.

Any significant differences in the grain sizes of the three raw materials lead to segregation in the furnace and hence variability of the specific electrical resistance of the burden. This has unwanted effects on the electrode heights in the furnace.

It is preferable that the raw materials used should have an unvarying chemical composition over a long period of time. This does not usually present any problems as far as the coke and silica are concerned. The variations in the P_2O_5, CaO, and SiO_2 contents of the phosphate sinter should be minimized.

Phosphate Sinters. As a rule, the phosphate rock is received from the mine in finely ground form, and then converted into lump form (sintered phosphate) by the phosphorus producer. Phosphate rock in broken pieces (produced by sieving) from Florida is now practically unobtainable in Europe. Lump phosphates from North Africa have a relatively high CO_2 content, which leads to unwanted bursting of the lumps in the furnace with consequent dust formation.

There are several processes for the manufacture of lump phosphate from finely ground phosphate rock. The earthy phosphates from Idaho can be fairly easily compressed into briquettes, and then heated to the sintering point in a Dwight–Lloyd bed (FMC). This causes the organic components of the phosphate to be burnt off, producing a sinter with good resistance to pressure and abrasion.

In the Monsanto process, the Idaho phosphate is ground and fed into a heated rotary furnace with 10 % dust from sintered phosphate. Pellets (nodules) are formed at the entrance to the furnace. These become sintered when the organic substances are burnt.

A process applicable to almost all types of phosphate rock is pelletization with a disk granulator followed by roasting on a moving grate (Hoechst, Allis Chalmers). Finely ground phosphate rock, to which a slurry for pelletizing has been added, is agglomerated into pellets of 1 – 2 cm diameter in a disk granulator. The slurry includes various amounts of, e.g., clay, dust from electrostatic precipitators used in phosphorus production, sodium silicate solution, sulfite liquor, and alkali-metal phosphates, depending on the type of phosphate rock used.

Roasting of the green pellets produced is carried out with Lepol roasters, Dwight – Lloyd bands, shaft furnaces, or rotary furnaces. Figure 4 shows a Lepol roaster [15]. The moist phosphate pellets pass via the feeder (a) into the drying zone (b) where they are dried by the exhaust gases from the combustion zone (c) and by the hot air from the cooling zone (e). The heat for roasting the dried pellets is provided by combustion of phosphorus furnace gas (85 – 90 % CO) in the burners (f), in which other fuels such as brown coal dust can also be used if there is insufficient gas. After the roasted pellets have passed through a dwell zone (d), they pass to the cooling zone (e) where they are cooled by drawing cold air through the bed of pellets. The process makes efficient use of the heat of combustion of the fuel gas.

The gases from the sintering process are removed by the extraction fan (j) via a spinningflow wet scrubber (i) or other gas washing equipment. The water used is slightly alkaline, containing $Ca(OH)_2$, and so absorbs HF and dust.

These gas cleaning methods, when used in new installations [16], reduce the impurities in the waste gases to levels not exceeding the following (mg/m^3):

Dust	50
Phosphoric acid	20
Fluorine compounds	5
Chlorine compounds	10
Sulfur dioxide	100
Phosphine	1

The filtration equipment that dedusts the air extracted from conveying equipment and mills gives dust levels in the exhaust air not exceeding 50 mg/m^3 in modern plants [16].

No wastewater is produced in this process, as the water used in the spinning-flow wet scrubber goes into the mix for granulation. The fines from the washer, together with the precipitated CaF_2, are recycled to the sintering process.

Coke. In general, dried metallurgical coke is used. The maximum moisture content should be 1 %, and the ash content as low as possible. A good quality coke has the composition: 90 % fixed carbon, 8.5 % ash, 1 % H_2O, and 0.5 %

Figure 4. Sintering plant with Lepol roasters

other volatiles. It is possible to replace a large proportion of this coke by cheaper petroleum coke. In this case, a higher proportion of organic impurities in the phosphorus must be accepted.

Silica. Deposits of silica as pebbles, gravel, or coarse sand containing > 97 % SiO_2 are fairly common, but not every phosphorus installation has such a deposit in the vicinity. Either higher costs of transporting the silica would have to be incurred, or the disadvantages of lower quality silica (high impurity levels, especially Fe_2O_3 content) would have to be accepted.

Composition of the Burden. The C/P_2O_5 ratio in the burden determines the extent of "complete reduction" of the phosphate, and the SiO_2/CaO ratio determines the flow properties of the slag. The carbon is consumed not only by the reduction of the pentavalent phosphorus in the phosphate, but also in reducing impurities such as oxides of iron. Therefore, it is not possible to calculate the coke requirement solely from the P_2O_5 content of the sintered phosphate. The P_2O_5 content of the slag must also be taken into account.

In phosphorus plants using phosphates (also coke and silica) from several suppliers, the effect of the composition of these phosphates on the production cost of the phosphorus is investigated before purchase. It is advantageous to use a computer to perform rapid calculations of quantities of raw materials required, furnace throughput, and amounts of byproducts, basing this on thermal data for the furnace and raw materials, and chemical compositions of the raw materials. For example, using

8.00 t phosphate pellets (31 % P_2O_5)
2.80 t silica (97 % SiO_2)
1.25 t coke (90 % fixed carbon)
0.05 t electrode material (uncalcined)

produces

1.00 t phosphorus
7.70 t slag
0.15 t ferrophosphorus (22 % P)
0.10 t dust from electrostatic precipitators
2500 m^3 off-gas (85 % CO)

4.2. The Phosphorus Furnace

The plant for production of white phosphorus (Fig. 5) consists of three parts:

A) the furnace with its electrodes, the raw material feeding equipment, the slag and ferrophosphorus tapping points, and the two vents for the furnace gas;
B) the electrostatic precipitators for removal of dust; and
C) the condensation equipment with the receivers for the phosphorus produced.

C) Condensation plant
m) Hot condensation; n) Cold condensation; o) Liquid phosphorus collection zone; p) Solid phosphorus collection zone; q) Submerged pumps

Small phosphorus furnaces have simpler equipment, i.e., dust settling chambers instead of electrostatic precipitators, and simplified condensation equipment without the high- and lowtemperature condensers shown in Figure 5. The liquid byproducts (slag and ferrophosphorus) are tapped off at different heights above the furnace floor.

The dust is removed from the furnace gas, which contains ca. 400 g/m^3 phosphorus and ca. 40 g/m^3 dust, by electrostatic precipitators. The temperature in this equipment must exceed the boiling point of phosphorus (280 °C), or the precipitators must be continuously heated. The furnace-gas temperature is usually higher in larger furnaces. This temperature should not exceed 550 °C, as the efficiency of electrostatic dedusting decreases at higher temperatures. The next stage in the process is the condensation of the phosphorus from the furnace gas. After the dust and phosphorus have been removed from the furnace gas, it can be combusted to provide heat for calcining the pellets and for the production of condensed phosphates.

The phosphorus furnace (Fig. 6) is a symmetrical alternating current furnace of the type used for the production of calcium carbide [17].

The furnace casing is made of sheet steel, the lower part lined with hard blocks of strongly calcined carbon, and the upper part with firebrick. The floor and lower part of the furnace are water-cooled. The furnace is circular, or shaped like an equilateral triangle with rounded corners. The three electrodes are situated at the corners of a regular triangle. The furnace top is made of corrosion-resistant steel, protected from the

heat of the furnace by a system of water-cooled coils and a covering made of clay and refractory cement. Furnace tops constructed of steel-reinforced refractory concrete without cooling coils have also proved to be satisfactory.

The furnace is equipped with Söderberg electrodes and has a flat furnace top which ensures that the submerged holder through which the current flows to the electrodes [18] and the electrodes themselves need not be of too great a length. The material of the Söderberg electrodes (20 – 25 % tar or pitch, 30 – 35 % coke dust, and 40 – 50 % granular calcined anthracite, softening point 110 °C) is heated by the electrical current and the furnace heat and is baked solid in the region of the contact plates. The electrode must become baked solid over its entire cross section when it is fed downwards to compensate for its consumption in the furnace (a few centimeters per hour). If the electrodes are not completely baked, there is a risk of breakage, especially with long electrodes. New electrode casings are welded on and electrode paste is added while the furnace is operating.

The electrode cross section depends on the electrode current, which for large phosphorus furnaces is 50 – 70 kA. For a current density of 4 A/cm^2, the corresponding electrode diameter is 1.30 – 1.50 m.

To avoid electrical losses in the secondary circuit, the transformers are situated close to the furnace. When single phase transformers are used, each one supplies two electrodes. The three electrodes of the furnace can be operated with a star or a delta connection, the latter being preferred. The secondary voltage is 200 – 650 V. The electrode current is kept fairly constant by automatically raising and lowering the electrodes; i.e., if the current increases, the electrodes are raised, increasing the electrical resistance between the electrodes and the furnace floor and hence reducing the current, and vice versa.

The furnace current is taken directly from the high voltage circuit [19]. Modern furnace transformers are provided with stepwise controllers which can increase the secondary voltage from a lowest value of ca. 130 V in 20 V steps up to a maximum of ca. 650 V.

The required quantities of sintered phosphate, coke, and silica are measured out by automatic weighing equipment, mixed by conveyors, and delivered into bunkers (Fig. 5), from which the burden slides down chutes into the furnace.

There are four feed chutes surrounding each electrode. The middle three combine to form a wider pipe (see Fig. 6). Since the furnace is operated under slight overpressure, nitrogen is continuously fed into the charging bunker, so that no carbon monoxide can reach the charging platform.

The lifetime of a phosphorus furnace is mainly determined by the durability of the carbon lining. Detailed monitoring of the state of the lining does not necessitate shutting down the furnace and completely emptying it. It is

achieved by incorporating radioactive sources at points where erosion is known to occur, a technique already used in steelworks [20]. Two or three ^{60}Co sources ($t_{1/2}$ 5.3 years) are used. These are inserted at various depths in the carbon bricks [21]. The intensities of the sources are chosen such that the radiation intensity outside the furnace decreases by one-third or one-half when the innermost source disappears. In this way, the thickness of the carbon lining can be continuously monitored. Furnaces with water-cooled floors have a longer working life than those without [22].

American Phosphorus Furnaces. American furnaces usually have a domed top, originally lined with refractory bricks, but usually made of cast concrete. Such furnaces can only be operated with prebaked electrodes. The original straight-line arrangement of electrodes gives rise to live and dead phases with three-phase electric current, which is a major disadvantage compared with furnaces with a symmetrical (i.e., triangular) electrode arrangement. The Tennessee Valley Authority (TVA) therefore also built furnaces with carbon or graphite electrodes in a triangular arrangement.

The baked carbon or graphite electrodes are bolted together with carbon nipples. However, the electrode is weakened at the junction point, and the furnace must be shut down to fit an extension piece by this method.

Whereas European furnaces usually have a carbon lining consisting of large blocks that must be fitted to within a millimeter, American furnaces floors are lined with carbon bricks. This type of lining is easier to install but less durable. It is very important to have a layer of rammed material between the carbon lining and the steel furnace casing.

In 1950 the TVA constructed a slowly rotating phosphorus furnace, which, however, did not become established [23].

After World War II, domed phosphorus furnaces with prebaked electrodes were built with power consumptions up to 70 MW.

Energy Consumption. Phosphorus manufacture in an electric furnace is energy intensive. The electrical current consumption for a 50 MW furnace breaks down as follows:

Energy consumption by the chemical reactions	ca. 45 %
Heat content of slag, ferrophosphorus, and furnace gases	ca. 40 %
Electrical losses, radiation losses, and cooling losses (cooling water)	ca. 15 %

Larger furnaces have smaller radiation losses. The composition of the phosphate rock and the purity of the other raw materials determine the amounts of slag and ferrophosphorus formed; these materials account for a considerable proportion of the power consumption. The specific energy consumption is minimized if the P_2O_5 content of the phosphate rock is high and the molar ratio of CaO to P_2O_5 is minimized.

Furnaces with a power consumption of 50 MW that use calcined phosphate rock have a specific power consumption of 12.5 – 13.5 kWh/kg phosphorus (excluding the phosphorus in the ferrophosphorus). Lump phosphate rock also contains calcium carbonate, which requires additional energy for its decomposition. Also, the CaO content must be controlled by the addition of silica, which increases the quantity of slag.

Gas Purification. The large-scale production of white phosphorus was first made possible by the use of electrostatic precipitators [24] to remove the dust from the furnace gases. After leaving the furnace, these gases first pass into an electrostatic gas purification system (usually two chambers in series) which removes 98 – 99 % of the dust particles. The gas velocity in the precipitators is ca. 0.5 – 0.8 m/s, and the dwell time in the electric field is ca. 10 s per precipitator. The vessels are heated to prevent condensation of phosphorus.

The separated dust settles on the floor of the electrostatic filter and is removed by a raking arm. It then falls into a slurrying vessel through tubes that dip into the slurry. The dust is slurried with water, and the slurry is used as a binder for the agglomeration of the phosphate rock in the sintering plant.

The composition of the dust (Table 3) shows that it is primarily formed in side reactions in the furnace.

Table 3. Examples of the compositions of dusts from electrostatic precipitators

Component	Dust composition, wt %		
	Hoechst	TVA	FMC
P_2O_5	16.9	28.5	38.4
CaO	12.2	10.7	16.3
F	3.6	5.9	1.1
SiO_2	36.6	18.1	19.6
Al_2O_3	2.4	3.4	1.2
Fe_2O_3	1.4	1.5	0.9
Na_2O	4.5	3.3	10.0
K_2O	11.3	16.2	10.0
C_{fix}	0.8	4.6	1.6

A small number of plants still operate without electrostatic precipitators, and the phosphorus is isolated by means of filter presses from the mixture of phosphorus and mud produced by the condensation process.

Condensation. The virtually dust-free furnace gases enter the condensation system at ca. 400 °C. There are hot and cold condensation stages. The hot stage operates above the melting point of phosphorus, and the cold stage below it. In both cases, the gas is washed with water, causing the phosphorus to condense from the gas stream.

The hot condensation equipment consists of one washing tower, or two in parallel, into which water at 50 – 60 °C is sprayed. The water collects with the condensed phosphorus in the lower part of the tower below the washing zone. The phosphorus is periodically pumped or siphoned off into heated storage vessels where it awaits further treatment while covered with a water layer. Part of the circulating water is continuously bled off and replaced, so as to remove impurities which would affect the quality of the product. These impurities consist mainly of fluorine compounds derived from SiF_4. This first forms hexafluorosilicic acid, which then hydrolyzes in the condensation equipment and stabilizes the mud formed by the dust and phosphorus. This interferes with the subsequent purification of the phosphorus (see Section 4.3).

The wash tower of the cold condensation stage uses water at 10 – 25 °C; the phosphorus condenses as a solid. The quantity of water required depends on the vapor pressure of the phosphorus in the hot condensation stage. The efficiency of recovery increases as the temperature of the water decreases (Fig. 7). The solid phosphorus that collects in the lower part of the tower is liquefied periodically by a heating system and pumped into storage tanks. The condensation water can be cooled by vacuum evaporation using steam jets [25].

Figure 7. Phosphorus content of furnace gas as a function of temperature
a) Amount of P_4 per cubic meter (STP) of furnace gas; b) Amount of P_4 per kilogram furnace gas

By efficient operation of the condensation equipment, the loss of phosphorus in the furnace gas can be less than 0.1 % of the total product. About 90 % of the furnace gas is used as a fuel in the sintering and phosphate salt plants, and 10 % is flared off. The dry furnace gas contains 85 – 90 % CO, 3 – 8 % N_2, 4 – 6 % H_2, 1 % CH_4, and 1 % CO_2. The calorific value is ca. 11.3 kJ/m^3.

Leaks in the equipment can allow CO to escape, endangering operating personnel. In the area of the furnace and up to the start of the hot condensation process, the danger is slight because phosphorus is also released, which ignites and causes combustion to form CO_2. The P_2O_5 that is also formed can lead to increased corrosion. Between the hot condensation process and the flaring off, and also at the open parts of the feed bunker, escapes of CO can occur. There are numerous sampling points where the gas is sampled continuously and automatically analyzed for CO. If the MAK value is exceeded,

a visible alarm is activated on the spot, and an audible one in the control room.

4.3. Purification of Crude Phosphorus

The phosphorus produced in the hot condensation equipment contains mud as an impurity. When the phosphorus is stored in liquid form, an intermediate layer appears between the phosphorus and the water layer. This contains up to 80 % elemental phosphorus, the remainder being water, and is stabilized by colloidal silicic acid.

All phosphorus plants face the problem of disposing of the phosphorus-containing mud. The practice of sending it to ponds where it oxidizes slowly is now obsolete. A certain amount can be used in the production of thermal phosphoric acid if the mud is homogeneously stirred into the phosphorus [26]. However, the quality of the phosphoric acid is reduced by this procedure, and the process is therefore seldom used.

The mud impurities can be removed from the crude phosphorus by centrifugation. A water-free mud with a high phosphorus content is obtained, which is recycled to the furnace (FMC).

Another proven method is to filter off all the phosphorus-containing product in a filter press. A wet residue with up to 30 % P is produced. This can be treated in three ways:

1) The residue is steam distilled in lined pressure vessels at a steam pressure of up to 10 bar [27]. The phosphorus is condensed as a liquid in tubular coolers, and the phosphorus-free residue is used in the phosphate pelletizing process along with the dust from the electrostatic precipitators.
2) The residue is fed into the furnace exit, whereby the hot gas vaporizes the water and phosphorus, and the solids are added to the dust from the electrostatic precipitators [28].
3) The mud is fed into the furnace. In this case, very strict safety precautions must be taken, and the rate of addition must be automatically controlled because pressure surges may occur if too much water enters the furnace.

In the United States, phosphorus distillation is also carried out in gas-heated rotary furnaces made of corrosion-resistant steel. Distillation processes that operate in the absence of water vapor have not proved successful owing to the formation of red phosphorus, which remains in the residue.

Phosphorus produced using Söderberg electrodes can contain up to 0.3 % organic impurities. This amount can be reduced to < 0.01 % by using adsorption media [29]. The residues so produced are treated in the way described above.

4.4. Treatment of Phosphorus-Containing Wastewater

The wastewater from the hot and cold condensation processes, the water from the storage tanks, and the water used for pressure transfer of the phosphorus must be treated to remove most of their phosphorus content before they are conveyed to the central wastewater treatment installation. Since wastewater always carries with it phosphorus mud, the purification problems resemble those which arise with crude phosphorus.

Wastewater is generated at a rate of 5 – 7 m^3 per tonne of phosphorus produced, and contains up to 1 g/L phosphorus, usually as a stable emulsion. Purification can be carried out by two methods:

1) The wastewater is passed through a settling tank to remove phosphorus, and another to remove coarse mud particles. The sediments are fed to the phosphorus filtration process. The water from the second settling tank is adjusted almost to neutrality, and a flocculating agent is added. All the solid materials are then separated out in a Dorr thickener. These solids are used in the pelletization of phosphate rock, or treated in the same way as the phosphorus mud. The clarified water from the Dorr thickener can be used for various purposes instead of fresh water (see below). Amounts surplus to requirements can be treated with chlorine solution to oxidize the dissolved phosphorus (3.6 mg/L) before discharge.
2) Another effective technique is filtration of the wastewater, a process similar to the filtration of crude phosphorus. Substances that stabilize phosphorus mud are kept at a low level in the filter. The phosphorus and water pass through the filter and separate quantitatively in a settling tank. The clarified

water contains essentially dissolved phosphorus only. It can be used without further treatment in place of fresh water: (1) as granulation water for slag granulation (making up for evaporation losses); (2) as the protective layer for storage of phosphorus; (3) to produce a slurry from the dust from the electrostatic precipitators; (4) as rinse water in the filtration of phosphorus; and (5) for cleaning storage vessels and tank cars. Water that is surplus to these requirements can be passed directly to a central wastewater treatment installation. If the waste-water is sent directly to the outfall, the dissolved phosphorus (3.6 mg/L) is most simply oxidized by chlorine bleaching. The residue is treated in the same way as that from phosphorus filtration.

4.5. Slag

For each tonne of phosphorus, ca. 8 t slag is also produced. The smooth tapping off of this slag at ca. 1350 °C determines to a considerable extent the production rate of a furnace. The furnace described above has two slag tapping holes to enable the slag to be tapped "symmetrically". The holes are changed over every few hours, and must therefore be wear-resistant. In the furnace described, they are water-cooled metal devices built into the carbon blocks of the furnace lining, and can be closed with a water-cooled metal plug.

As the slag leaves the furnace, it is granulated by quenching in a water jet, forming vitreous pseudo-wollastonite, $CaSiO_3$, and cuspidine, $Ca_4Si_2O_7F_2$. This granulated silicate slag is a valuable byproduct. It is used as a construction material for dumping grounds, and a small amount is milled for use as a foundry chemical.

If there is an outlet for the slag in lump form for the construction of embankments or roads, it is poured while molten into beds where it cools slowly.

Conversion of the slag into lightweight building blocks is not feasible because of the slight radioactivity of the uranium originating from the phosphate rock.

Various fume emissions are associated with slag tapping and granulation. Fluorine compounds, phosphoric acid, chlorine compounds, and water vapor are emitted. The use of wet scrubbing in modern plants enables emissions to be kept below the following levels [16]:

Phosphoric acid (as P_2O_5)	20 mg/m^3
Fluorine compounds (as F^-)	5 mg/m^3
Chlorine compounds (as Cl^-)	10 mg/m^3

The yield of phosphorus is critically dependent on the P_2O_5 content of the slag. Therefore, not only must the analysis of the raw material be monitored, but continual analysis of the slag produced is also essential. With good furnace operation, the P_2O_5 content of the slag can be held to 1.0 %. The slag modulus (weight ratio of SiO_2 to CaO) is 0.8 – 0.9. Examples of slag compositions are given in Table 4.

The heat of the slag accounts for ca. 30 % of the electrical energy consumed by the furnace. Attempts to recover this energy have so far been unsuccessful.

4.6. Ferrophosphorus

As well as phosphorus, the furnace produces ferrophosphorus, which collects under the slag. The ferrophosphorus is tapped off, usually once per day, through a hole in one of the carbon blocks, which is opened with an oxygen lance and closed again with a clay plug. The ferrophosphorus, together with some slag, flows into a crucible, from which the lighter slag overflows into a bed of sand. When the tapping off is completed the ferrophosphorus is poured from the crucible into a bed of sand, and, after cooling, is broken into pieces [30].

Every time the ferrophosphorus is tapped off, its radioactivity is measured. If a ^{60}Co source becomes dislodged as the furnace lining wears away, the ^{60}Co is transferred quantitatively into the ferrophosphorus. The radiation supervisor decides in each case whether the ferrophosphorus should be sold, placed in short term storage, or stored indefinitely.

Fume extraction operates in the areas surrounding the furnace tapping and sand beds. The waste gases are purified by wet methods. For new installations, the following emission levels are not exceeded [16]:

Dust	50 mg/m^3
Phosphoric acid (as P_2O_5)	20 mg/m^3

Table 4. Composition of furnace slags (wt %)

Process	P_2O_5	CaO	F	SiO_2	Al_2O_3	Fe_2O_3	Na_2O	K_2O
Hoechst	1.0	48.2	2.8	43.3	2.4	0.2	0.5	0.2
TVA	1.0	50.0	2.6	39.5	6.2	0.3	0.6	0.7
FMC	1.0	48.2	2.6	38.3	5.9	0.1	0.0	0.0

Depending on the method of furnace operation, the ferrophosphorus contains between 15 and 28 % P, corresponding approximately to the formula Fe_2P. The more extensively the phosphate rock is reduced, the more silica is converted into silicon, which reduces the phosphorus content of the ferrophosphorus. The combined content of P and Si is 25 – 30 %. Ferrophosphorus with a low silicon content (< 3 %) has a fairly good market potential, and is used in the manufacture of phosphorus-containing alloys. The grades with a low phosphorus content are not in great demand, but can be used in smelting low-phosphorus iron ores or to increase the P_2O_5 content of basic Thomas slag.

Ferrophosporus is stored in the open, and supplied either loose or in drums. The other metals present in the ferrophosphorus in addition to the Fe, P, and Si depend on the composition of the phosphate rock. Examples of compositions of ferrophosphorus are given in Table 5.

Valuable metals such as vanadium, can be recovered economically from the ferrophosphorus if they are present in unusually high concentrations. Vanadium is recovered together with chromium by blowing with oxygen. Both metals accumulate in the slag.

Older processes for treating ferrophosporus, which are however no longer of importance, are described in [31].

4.7. Yields

Modern pelletizing and sintering installations operate with a 99 % yield based on the phosphate rock used. Only dust losses and losses during transport and handling occur, the former being very small with modern dust filters. The recycling of the dust from the electrostatic precipitators can involve slight yield losses if it contains elemental phosphorus which burns to form P_2O_5. This is not completely absorbed by the water in the scrubbers attached to the sintering furnace.

If ZnP becomes concentrated in the dust from the electrostatic precipitators (due to a high Zn content in the phosphate rock), to such an extent that it cannot be recycled, it must be used in other ways; e.g., it is oxidized and then used in fertilizers. This also represents a loss of yield.

Furnace operation involves higher losses than sinter production. Good reduction of the P_2O_5 in the sinter gives a slag containing on average 1.3 % P_2O_5, corresponding to a loss of yield of ca. 5 %. The ferrophosphorus byproduct represents an average loss of yield of ca. 3 %.

When the excess furnace gas is flared off, phosphorus is burnt as well as CO, the amount depending on the temperature of the cold condensation water. As only ca. 10 % of the total furnace gas is flared off, the associated yield loss only amounts to a maximum of 0.01 %. Most of the gas (ca. 90 %) is used in the phosphate sintering plant or for the production of condensed phosphates. Here, the phosphorus in the gas is burnt and used again.

Modern equipment for dewatering and treating phosphorus mud produces phosphorus mainly in elemental form. In earlier processes, a large proportion of the recovered phosphorus was oxidized. The loss of yield is <0.1 %.

Overall, the total yield in a modern phosphorus production plant is ca. 91 %.

The largest loss of yield is associated with the slag, so that it might appear advantageous to increase the coke rate in order to reduce the P_2O_5 content of the slag. However, this causes increased reduction of silica, thus increasing the Si content of the ferrophosphorus and reducing the P content. Ferrophosphorus of this quality is practically unmarketable, and, moreover, does not separate well from the slag. This leads to difficulties when tapping and granulating the slag. The increase in electricity consumption for the reduction of the SiO_2 must also be taken into

Table 5. Composition of ferrophosphorus (wt %)

Process	P	Si	Ti	Cr	V	Mn
Hoechst high percentage	26.6	0.3	4.5	0.2	0.6	0.5
Hoechst low percentage	20.0	9.5	5.8	0.2	0.5	0.7
TVA	24.0	1.7	1.7	0.2	0.3	1.1
FMC	27.1	0.2	0.3	4.5	5.4	0.5

account. In practice, it is not possible to reduce the P_2O_5 content of the slag below 1 %.

5. Production of Red Phosphorus

The conversion of white phosphorus into the more stable red form is an exothermic reaction. It must therefore be carried out under controlled conditions.

The process which has been used in Germany since 1936 in Bitterfeld and since 1953 in Knapsack is based on a Russian invention in which the phosphorus is converted in an open reactor. However, in Bitterfeld and Knapsack, closed reactors with charges of ca. 6 t are used (Fig. 8).

The reactor consists of a thick-walled iron rotary furnace resting on two hollow shafts with a driving mechanism, and surrounded by an air bath. It contains a small charge of steel balls. The white phosphorus in the reactor is first heated by the gas-heated air bath to 100 – 180 °C to drive off the water completely. Evaporating phosphorus is recovered in a condenser. After removal of the water, the reactor is sealed and heated to 270 – 275 °C over a period of ca. 24 h, whereby ca. 70 % of the white phosphorus is converted to the red form. A further increase in temperature causes the remainder to be converted very rapidly, with accompanying increases in pressure and temperature. The reactor is then cooled and filled with water, and the phosphorus is ground to the desired fineness.

In addition to the fact that the charge is relatively large, an important advantage of this process is that the phosphorus is not produced in the form of hard cakes, as in earlier autoclave processes, but as a powder.

In a modified version of this process, the full charge is not added to the cold reactor. Instead, white phosphorus is pumped in small batches into the dry reactor, which has been brought up to the reaction temperature. A large fraction of the phosphorus is converted directly into the red form. The advantages of this method are higher throughput and greater safety because the quantity of white phosphorus present in the reactor at any time is small [32].

The aqueous suspension of red phosphorus is steam heated in stirred vessels, and the remaining white phosphorus (ca. 0.1 %) is decomposed by adding sodium hydroxide solution. The phosphorus is filtered off and washed in rotary cellless filters or filter presses. The phosphorus is then continuously dried in steam-heated rotary or shelf dryers under a slight positive pressure of nitrogen. The nitrogen is circulated to remove the water vapor from the drying equipment. Air-entrained dust is removed in scrubbing towers and returned to the process.

The conversion and drying of the red phosphorus must be precisely controlled to avoid severe accidents. The pressure and temperature in the reactor can rise sharply if the conversion is uncontrolled. The oxygen content of the nitrogen in the shelf dryer must be controlled to avoid spontaneous explosive ignition of the red phosphorus. The explosion limit is at 3.5 % oxygen; in practice, the concentration of oxygen in the nitrogen is usually limited to ca. 1.5 %.

In the course of the treatment process (after heating to remove the last of the white phosphorus and up to the drying process), the red phosphorus can be treated to coat the surface of the grains with substances to perform various functions, e.g., to stabilize the red phosphorus (against P_2O_5 formation), to consolidate or "phlegmatize" (to prevent dust formation), to give hydrophobic properties, or to produce special properties to enable the material to be incorporated into plastics. The major producers of red phosphorus have developed special grades for the various applications in collaboration with their customers (see Section 6.2. and Chap. 7).

Figure 8. Manufacture of red phosphorus
a) Phosphorus storage; b) Reactor; c), d) Treatment of phosphorus – water mixture; e) Filtration; f) Conveyor; g) Dryer; h) Air classification and sieving; i) Predelivery storage

The finished and dried red phosphorus is packed in polyethylene bags and steel drums containing up to 50 kg, or in stainless steel containers (DIN 1.4301) containing up to 1.5 t. Grinding, sieving, air classification using nitrogen, and filling are all carried out in a nitrogen atmosphere.

To reduce the conversion time and produce an extremely fine product, TVA has suggested that the reaction should be carried out only to ca. 50 % completion, the unchanged white phosphorus then being removed by vacuum distillation [33].

Albright & Wilson [34] and Rinkagaku Kogyo [35] use a similar method to obtain a red phosphorus that is easier to handle. Erco Industries have applied for patent protection in Europe for a process in which the heat of the conversion of white to red phosphorus is removed by the evaporation of the white phosphorus during the conversion. About 40 % of the white phosphorus is recovered as red phosphorus, which is produced in a special amorphous form [36].

During the production of red phosphorus, wastewater and fumes are produced which have to be treated. If the production plant is part of a factory where white phosphorus is manufactured and treated, this is fairly simple.

The wastewater that has been in contact with white phosphorus is taken to the wastewater treatment plant attached to the phosphorus production plant, and the wastewater from the red phosphorus plant is filtered to remove the red phosphorus and taken to the central water treatment plant where reducing compounds are removed, e.g., by oxidation with air.

Air is extracted from the area of the reactors and from the vats where white phosphorus is treated with hot NaOH. This air must be oxidized, and the P_2O_5 produced must be absorbed. This is achieved by using the air for the combustion of phosphorus in a phosphoric acid plant.

6. Quality Specifications, Storage, and Transportation

6.1. White Phosphorus

Commercial white phosphorus, as produced by the electrothermal process using Söderberg electrodes, contains ca. 99.4 % P. The main impurities are water (0.3 %), which is taken up during condensation and storage, and benzene-soluble organic components, mainly produced during the baking of the Söderberg electrodes. The other impurities originate from the raw materials (Table 6). Arsenic is not dissolved in phosphorus, but replaces it in the phosphorus lattice, so that it is practically impossible to remove this impurity on an industrial scale.

Table 6. Analytical data for white phosphorus

Impurity	Content, wt %	
	Technical grade	Purified
Benzene-soluble organics	0.3	0.01
H_2O	0.25	0.10
As	0.01	0.01
S	0.05	0.05
Fe	0.005	0.005
Pb	0.0005	0.0005

Purified phosphorus with a reduced content of benzene-soluble organics is also produced (Table 6).

White phosphorus is usually stored as a liquid in heated vessels. It is constantly kept covered with warm water, and the free space above this is ventilated with nitrogen, so that no air is present in any part of the vessel.

Tonnage quantities are transported in heated tank cars with special connectors and valves. These tank cars normally contain only nitrogen at a slight positive pressure, but, if required by the customer, a protective water layer is also included.

For export, phosphorus is poured into internally coated steel drums with bungs. Small quantities are packed in wedge-shaped pieces (ca. 1 kg each) in drums with swaged-on lids. These drums always contain a protective water layer. The space above the liquid must in all cases amount to 2 % of the total volume at 60 °C.

The following transport regulations apply:

Road:	GGVS/ADR Class 4.2, No. 1
Rail:	GGVE/RID Class 4.2, No. 1
Sea:	ADNR Class 4.2
Air:	IATA-DGR not permitted
UN no.:	1381/I (phosphorus as cast blocks)
UN no.:	2447/I (phosphorus in wedge form)

6.2. Red Phosphorus

Red phosphorus, after the conversion process but before any special treatment, has the composition shown in Table 7.

The content of benzene-soluble organics and water is decreased in the red phosphorus compared with the original white phosphorus (furnace quality), while the iron content increases due to abrasion of the steel balls and of the reactor itself.

Heating with sodium hydroxide solution reduces the white phosphorus content to < 0.01 % (absence of Mitscherlich reaction [37]).

Depending on the intended application of the red phosphorus, the surface of the particles is coated by treating with various substances:

1) $Mg(OH)_2$ or $Al(OH)_3$ for stabilization (by combining with any P_2O_5 that may be formed).
2) Silicones for prevention of dust formation
3) Waxes to confer hydrophobic properties
4) Synthetic resins to condition for use in fireproofing plastics.

Table 7. Analytical data for red phosphorus

Component	Content, wt %
Benzene-soluble organic substances	0.1
H_2O	0.04
As	0.01
S	0.05
Fe	0.08
Pb	0.0005
H_3PO_4	0.05
White phosphorus [a]	0.1

[a] Decreases to 0.01 % white phosphorus on heating with sodium hydroxide solution.

The treatment of red phosphorus can involve various combinations of these possible techniques to suit customer demand, and affects the composition of the end product in a manner for which no general analysis can be given.

For many kinds of red phosphorus "products" (including various size distributions), storage is not possible. Each product is immediately packed under nitrogen in the customer's container.

Red phosphorus is packed in polyethylene bags under nitrogen, and these are packed in steel open-topped drums with lids. For tonnage quantities of red phosphorus, stainless steel containers are used. The following regulations apply:

Road:	GGVS/ADR	Class 4.1, No. 8
Rail:	EVO/RID (Appendix C)	Class 4.1.
Sea:	IMDG Code	Class 4.1.
Air:	IATA-(DGR)	No. 1413
UN no.:	1338	

7. Uses

White Phosphorus. In 1988, world production of white phosphorus was 750 000 t, of which ca. 83 % was used in the production of phosphoric acid, and of this ca. 50 % was used to manufacture phosphates for detergents. The remaining 50 % of the phosphoric acid was used to make phosphates for foodstuffs, pharmaceuticals, and animal feeds, a further fraction was used directly in foodstuffs, and some was used for surface treatment of metals.

The remaining 17 % of the phosphorus produced was used in the manufacture of phosphorus halides (PCl_3, $POCl_3$, PCl_5), P_2S_5, red phosphorus, P_2O_5, and metallic phosphides (e.g., magnesium phosphide and phosphor bronzes).

Red Phosphorus. The classical uses for red phosphorus are in the striking surface of match boxes and in pyrotechnics.

A considerable proportion is converted to metal phosphides such as aluminum phosphide. This has an important application as a pest control agent in grain silos (liberation of PH_3), especially in India and China.

A continually increasing application is in the manufacture of various flameproofing preparations, replacing chlorine-containing substances. It is incorporated in synthetic polymers such as condensations resins, polyamides, polyesters, polyepoxides, and polyurethane foams.

High-purity red phosphorus produced by distillation of PCl_3, reduction to white phosphorus, and conversion to the red form, is important in the manufacture of semiconductors, especially gallium phosphide (for laser diodes), although the quantities are very small.

8. Economic Aspects

White Phosphorus. World production of white phosporus increased from only a few thousand tonnes at the end of the 1900s to 10^5 t in 1939. By 1974, the year of maximum world production, this had increased to ca. 8.2×10^5 t. The reason for this large increase was the demand for tetrasodium diphosphate and especially pentasodium triphosphate, which were manufactured exclusively from thermal phosphoric acid and used principally in detergents.

During the 1970s, but initially in the United States in 1969, the use of phosphates in detergents decreased in the western World as a consequence of new regulations limiting the use of phosphates to reduce the eutrophication of inland waters. In the same period, energy costs (electricity and coke) increased, so that the cost of white phosphorus increased sharply, and purified wet phosphoric acid then became strongly competitive with thermal phosphoric acid produced from elemental phosphorus. Both these events caused a slowing down and eventual stagnation of the production of white phosphorus, so that phosphorus furnaces were closed down (see Fig. 9 and Table 8 [38]).

Figure 9. Phosphorus production, 1953 – 1988
a) World production; b) U.S. production

According to available information, the former Soviet Union and China, which are not linked to the world market, have considerably increased their capacity during the last 12 years (Table 8) [38].

The world market price of white phosphorus in 1988 was ca. 1640 €/t. European manufacturers are now, as in the past, increasingly at a disadvantage compared with the United States because of the large distances over which the phosphate rock is transported and the high costs of electricity and coke.

Red Phosphorus. World production of red phosphorus in 1988 was ca. 6500 t, and the world market price was ca. 4600 €/t. No reliable information concerning world capacity is available. Red phosphorus is manufactured in seven coun-

Table 8. Producers of white phosphorus and their capacities (1989)

tries, the three largest producers being Germany, India, and China.

9. Toxicology

Whereas red phosphorus is hardly absorbed at all on oral ingestion and therefore has very low toxicity, fat-soluble white phosphorus is highly toxic. However, experiments on animals have shown that the effects of red phosphorus on the liver and kidneys are similar to those of white phosphorus [39].

Kinetics and Metabolism. White phosphorus can be absorbed through the skin and via the respiratory and gastrointestinal tracts. In rats, the highest retention five days after oral administration was found in the liver, skeletal musculature, gastrointestinal tract, blood, and kidneys. In the body, phosphorus is oxidized to phosphate [39]. Following a single oral ingestion of isotopically labelled phosphorus, rats excreted about half of the radioactivity in the urine and about one-third in the feces within five days [40].

Acute Toxicity. The toxicity of white phosphorus is probably a result of its powerful reducing properties [39], which interfere with intracellular oxidation processes. In humans, as little as 15 mg can cause toxic effects. The lethal dose is reported to be 50 – 100 mg, corresponding to ca. 1 mg/kg of body weight [41–43]. The course of poisoning following oral ingestion is characterized by initial severe irritant effects on the digestive tract. The symptoms consist of stomach pains, nausea, vomiting, and shock. The stomach contents have a garliclike odor and may phosphoresce in the dark [42]. At this stage, death can occur through cardiovascular failure. Otherwise, the symptoms generally become less severe within one to three days. Following this recovery period, the symptoms of resorptive toxicity appear. Severe damage to liver cells occurs, and within a few days acute yellow hepatic atrophy can lead to death. The first symptoms manifest themselves as diarrhoea, vomiting (frequently blood-stained), sensitivity to pressure in the region of the liver, and increase in transaminases and bilirubin [44]. Kidney damage and cardiovascular changes also occur [39], [42]. Vascular damage leads to petechial and ecchymotic hemorrhages in the skin and mucous membranes, as well as hemorrhages in other organs [45], [46]. Collapse ultimately occurs, due partly to the toxic effects on the muscles of the heart [47], [48], and partly to liver and vascular damage.

Investigations of the acute oral toxicity in rats and mice gave LD_{50} values of 3 – 5 mg/kg [40]. Here also the picture of acute poisoning is principally characterized by liver damage (fatty degeneration) [49].

If white phosphorus comes into contact with the skin or eyes, serious burns result [40]. Experiments on animals have shown that dermal application can lead to liver and kidney damage [39]. Phosphorus vapor has an irritant action on the respiratory tract [40].

The treatment for acute oral phosphorus poisoning consists of immediate gastric lavage with 0.1 % potassium permanganate solution (oxidation of phosphorus to phosphoric acid) and high doses of animal charcoal, or gastric lavage with 0.2 % copper sulfate solution, which forms insoluble copper phosphide. The resorption of phosphorus can be prevented by administration of liquid paraffin. Additionally, treatment for symptoms of liver damage, shock, and dehydration is advisable [44]. The results of animal experiments [50], [51] suggest that 5 % sodium hydrogencarbonate with 3 % copper sulfate in 1 % hydroxyethylcellulose with the addition of 1 % lauryl sulfate could be suitable for the local treatment of burns caused by white phosphorus.

Subchronic and Chronic Toxicity. Chronic poisoning by phosphorus has become seldom. The first indications of chronic phosphorus poisoning are anemia, loss of appetite, gastrointestinal distress, chronic cough, garlic-like odor of the breath, and pallor [40]. More prolonged exposure leads to chronic atrophy of the bones. If the bones (usually of the jaw) then become infected, necrosis can occur [52]. The first signs of damage to the jaw consist of toothache and salivation, followed by tooth loss and swelling of the jaw [40].

Subchronic intake of phosphorus in the feed causes pathological changes to the bones of rats and rabbits (retardation of longitudinal bone growth and disturbance of dentine calcification in rats). Changes to the bones varying with dose rate also take place after chronic subcutaneous application of phosphorus to rats and guinea pigs, and also to a lesser extent after chronic administration in the feed in rats. Rats exhibited dose-related reduction of survival rates in both studies. With dogs, subchronic subcutaneous application of phosphorus led to fatty degeneration of the liver, kidney degeneration, changes in clinical-chemical parameters, and loss of weight [40]. Liver damage, including cirrhosis, was also observed following chronic oral administration [39].

Reproductive Toxicity. The administration of phosphorus to male and female rats before and after mating, and during gestation, led to the death of some female animals, apparently caused by birth difficulties. The number of live births was reduced [40].

Legal Requirements. The MAK value for white phosphorus is 0.1 mg/m^3 [53]. In the United States, a TLV-TWA value of 0.1 mg/m^3 has been prescribed [54].

1. Phosphorus – Oxygen Compounds

Approximately one decade after the discovery of phosphorus, R. BOYLE in 1680 obtained its most important oxide, the pentoxide, by combustion of phosphorus. In 1777, LE SAGE prepared phosphorus trioxide mixed with other phosphorus oxides, and in 1886 phosphorus tetroxide was described by T. E. THORPE and A. E. TUTTON as a compound distinct from P_2O_5 and P_2O_3.

The existence of P_4O, P_2O, PO, and PO_2 in an argon matrix has been demonstrated spectrographically. The PO molecule has also been detected in the vapor phase. However, these compounds are unstable under normal conditions.

A suboxide of phosphorus with the approximate formula $(P_4OH)_n$ is produced by the action of oxygen on phosphorus in a water vapor atmosphere at 80 – 160 °C.

The phosphorus oxides are formed in strongly exothermic reactions between the elements, and occur in dimeric and polymeric form. The only industrially important oxide of phosphorus is the pentoxide.

1.1. Phosphorus Pentoxide

Physical Properties. Phosphorus pentoxide [*1314-56-3*], tetraphosphorus decaoxide, P_4O_{10}, M_r 141.95, the anhydride of orthophosphoric acid, is at room temperature a fluffy, white, snowlike, odorless powder that sublimes under standard pressure at 360 °C, and separates as hexagonal crystals (H form) on slow cooling of the vapor. More rapid cooling produces an amorphous form. Commercial phosphorus pentoxide consists mainly of the H form, though it usually also contains some of the amorphous

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a19_527

powder form. Both the vapor and the solid consist of P_4O_{10} molecules.

Each phosphorus atom is tetrahedrally surrounded by four oxygen atoms.

P_4O_{10}

At a pressure of 0.5 MPa, the crystalline H form can be melted to give a colorless, clear liquid of low viscosity and high vapor pressure. Liquid phosphorus pentoxide also consists of P_4O_{10} molecules.

If hexagonal P_4O_{10} is heated to 400 °C in a closed system, after 2 h a metastable orthorhombic modification (O form) is produced. This has a melting point of 562 °C, and consists of chalky aggregates of small crystals. If the H form is heated to 450 °C for 24 h under the same conditions, a stable orthorhombic O′ modification is obtained consisting of readily cleavable aggregates and having a melting point of 580 °C. Both crystal forms are composed of $(P_2O_5)_x$ layers in which each phosphorus atom is tetrahedrally surrounded by four oxygen atoms. They melt to form a viscous involatile liquid, which on quenching gives a vitreous modification with a melting point of 565.5 °C.

After exposure to light, phosphorus pentoxide phosphoresces with a green color. As the temperature is reduced, the intensity of the light increases, reaching a maximum at −180 °C.

Chemical Properties. The best known property of P_4O_{10} is its remarkable tendency to take up water. Below 100 °C, it is the strongest known dehydrating agent. The water vapor partial pressure of the hydrolysis product is $<10^{-4}$ Pa at room temperature. However, the surface of the phosphorus pentoxide soon becomes covered with a film of polyphosphoric acid, completely isolating the reactive oxide underneath. Therefore, when P_4O_{10} is used as a drying agent, it should be distributed over a large surface area (e.g., on glass wool). Reaction with water first forms cyclic tetrametaphosphoric acid $(HPO_3)_4$, which, on taking up a further H_2O molecule, undergoes cleavage to give the straight-chain tetraphosphoric acid $H_6P_4O_{13}$. Further hydrolytic decomposition produces diphosphoric acid $H_4P_2O_7$ and then orthophosphoric acid. Reaction with ethers causes cleavage of different P−O bonds to those cleaved by water, giving esters of isotetrametaphosphoric acid.

Alcohols react with P_4O_{10} to form mono- and diesters of orthophosphoric acid.

Phosphorus pentoxide is also used for the dehydration of chemical compounds. For example, anhydrous nitric and sulfuric acid yield the acid anhydrides N_2O_5 and SO_3, while acid amides are dehydrated to form nitriles.

Production. The combustion of phosphorus in an excess of dry air or oxygen produces phosphorus pentoxide:

$$4\,P + 5\,O_2 \rightarrow P_4O_{10} \quad \Delta H = -2994.6\,\text{kJ}$$

On the industrial scale, pure liquid phosphorus is introduced in finely divided form into a special burner containing dry, oxygen-enriched air at elevated pressure. Sometimes further dry air is added during combustion.

The combustion chambers can be the same as those used in the production of phosphoric acid (→ Phosphoric Acid and Phosphates), or can be of a special type [1]. They are made of stainless steel, and the walls of the combustion chamber are protected from the intense heat of reaction by intensive water cooling. The combustion temperature is ca. 2000 °C. Some of the phosphorus pentoxide vapor deposits on the cold wall of the combustion chamber, forming a vitreous coating which protects the wall from corrosion. This coating sublimes off at temperatures above 605 °C.

The phosphorus pentoxide vapor leaves the combustion chamber at ca. 900 °C, and passes through a pipe into a dwell chamber. The output of the production unit depends to a large extent on the intensity of cooling of this part of the apparatus. Up to 95 % of the P_4O_{10} produced collects in the dwell chamber as a white,

dry powder. Approximately 5 % of the product is lost in the off-gases, which contain 7 % oxygen and have a temperature of 120 °C at the dwell chamber exit. The gases are scrubbed with phosphoric acid, e.g., in a Venturi apparatus, to remove the P_4O_{10}. If the phosphorus pentoxide plant is operated near to a phosphoric acid plant, the off-gases from phosphorus pentoxide production can be fed directly to the acid plant [2].

Coarse particles of agglomerated phosphorus pentoxide of low reactivity can be obtained if the vapor is condensed in a fluidized bed in which water-cooled stainless steel cold fingers or spiral condensing tubes are immersed [3]. The conventional condensation system described above can also be used to give various pentoxide qualities by varying the condensation conditions [4].

The reactivity of phosphorus pentoxide can be reduced by heat treatment [5].

In all the cases described above, the phosphorus pentoxide produced can be shown by X-ray analysis to have a hexagonal crystalline form.

Quality. Phosphorus pentoxide produced in modern plants contains 99.8 % P_4O_{10} and < 0.01 % P_4O_6. It does not even decolorize a pale pink solution of $KMnO_4$ after several hours, showing that oxidizable substances (elemental phosphorus, lower phosphorus oxides) are not present. Other data:

Arsenic	< 50 ppm
Iron	< 5 ppm
Fluorine	< 5 ppm
Heavy metals (e.g., Pb)	< 1 ppm
Residue insoluble in water	<0.02 %
Color	pure white
Bulk density	ca. 0.7 kg/L

The technical product was formerly purified by sublimation, but is now produced directly with the required purity.

Uses. Apart from its use in the production of phosphoric acid, phosphorus pentoxide is mostly used in organic chemistry for dehydration reactions. It is also used as a drying agent for solids, liquids, and gases with which it does not react. It is a convenient medium for absorption of moisture in vacuum systems, e.g., in the production of electric light bulbs.

The production of phosphoric acid esters from phosphorus pentoxide is described in → Phosphorus Compounds, Organic. The addition of ca. 0.5 % phosphorus pentoxide to asphalt increases its softening temperature and prevents brittleness at low temperature [6]. The production of ammonium polyphosphate for fireproofing is described in [7], [8].

1.2. Other Phosphorus Oxides

Phosphorus trioxide [*12440-00-5*], tetraphosphorus hexaoxide, P_4O_6, M_r 219.88, the anhydride of phosphonic acid, forms soft, waxy, colorless, monoclinic crystals, ϱ 2.135 g/cm^3, *mp* 23.8 °C, *bp* 175.3 °C. It has an unpleasant smell and is very poisonous. It can be crystallized from carbon disulfide, and is slightly soluble in benzene, carbon tetrachloride, chloroform, and dioxane. White phosphorus is soluble in phosphorus trioxide (ca. 1.7 g/100 g P_4O_6 at 25 °C). Phosphorus trioxide consists of P_4O_6 molecules in both the vapor and the solid.

Phosphorus trioxide is slowly oxidized to phosphorus pentoxide by air at room temperature, and spontaneously ignites on heating to 70 °C. When dissolved in cold water with vigorous agitation to give a dilute solution, exclusively H_3PO_3 is formed; without agitation, H_3PO_4 and an undefined solid yellow substance are formed in addition to H_3PO_3. In hot water, the reaction becomes violent, forming phosphine, phosphoric acid, and red phosphorus.

Phosphorus trioxide reacts with chlorine and bromine to form halides. Reaction with iodine in a sealed tube gives P_2I_4. With HCl, phosphonic acid and phosphorus trichloride are formed [9].

Production. When white phosphorus is burnt at 46 – 50 °C in a silica tube in the presence of a restricted amount of air, phosphorus trioxide is formed in a highly exothermic reaction.

$$4\,P + 3\,O_2 \rightarrow P_4O_6 \quad \Delta H = -1646.4\,\text{kJ}$$

This method, described by Thorpe and Tutton, was later improved to give yields of 50 – 60 % [10]. The phosphorus trioxide produced always contains residual elemental phosphorus, which can be converted into the red form by irradiating with ultraviolet light [11], and can

then easily be removed. A continuous process for the production of P_4O_6 is described in [12].

Attempts to produce phosphorus trioxide by reaction of phosphorus trichloride with phosphonic acid have so far been unsuccessful.

Phosphorus trioxide has not yet gained industrial importance.

Phosphorus Tetroxide [*12137-38-1*], diphosphorus tetraoxide, P_2O_4, M_r 125.95, can be sublimed at high temperatures, forming colorless, transparent crystals, ϱ 2.54 g/cm^3. It is the mixed anhydride of phosphonic and orthophosphoric acid, and dissolves readily in water with liberation of heat to form H_3PO_3 and H_3PO_4. Like P_2O_5, it is dimeric in the vapor phase.

Phosphorus trioxide disproportionates on heating at 210 °C for several days into red phosphorus and phosphorus tetroxide. Other phosphorus(III,V) oxides are also formed.

Tetraphosphorus heptaoxide P_4O_7 and tetraphosphorus nonaoxide P_4O_9 are III/V oxides formed as side products in the disproportionation of phosphorus trioxide to phosphorus tetroxide [13], or can be obtained by the controlled reduction of phosphorus pentoxide with red phosphorus [14]. Of the two crystalline forms, the rhombic α-form contains P_4O_8 and P_4O_9 molecules, while the monoclinic β-form consists of P_4O_7 and P_4O_8 molecules. The pure compounds P_4O_7, P_4O_8, and P_4O_9 have not been isolated.

A blue-violet solid with the composition P_2O_6, probably a phosphorus peroxide, is produced when a mixture of P_2O_5 vapor and hydrogen is subjected to an electric discharge under reduced pressure at 150 – 220 °C. The peroxide reacts with water to form peroxodiphosphoric acid ($H_4P_2O_8$). The violet solid is stable in the absence of water [15].

1.3. Phosphorus Acids and their Salts

(For phosphoric acid, see → Phosphoric Acid and Phosphates)

The oxo acids with the general formulae H_3PO_n (ortho acids) and $HPO_n{}^{-1}$ (meta form) and the diacids with the general formula $H_4P_2O_n$ ($n = 4 - 8$) are known, and are listed in Table 1 in order of increasing oxidation state of the phosphorus.

In aqueous solution, the anions of phosphinic, phosphonic, and phosphoric acids are present in the following forms, as shown spectroscopically.

Phosphate Phosphite Hypophosphite

The hypophosphite (phosphinite) anion contains two hydrogen atoms that cannot be neutralized by alkalies. Phosphinic acid is thus monobasic. Likewise, phosphonic acid is dibasic and phosphoric acid tribasic.

In addition to the simple phosphoric acids, there are many polyphosphoric acids with the general formula $H_{n+2}P_nO_{3n+1}$ with three or more phosphorus atoms in the molecule and containing P–O–P bonds, as well as acids with a lower oxygen content that contain P–P bonds:

Diphosphonic acid, $H_4P_2O_5$, with the anion

Diphosphoric acid, pyrophosphoric acid, $H_4P_2O_7$, with the anion

Triphosphoric acid, $H_5P_3O_{10}$, with the anion

A representative of the low oxygen polyphosphoric acids is hypodiphosphoric acid, $H_4P_2O_6$, with the anion

Table 1. Mono- and diphosphoric acids

Oxidation state	Acids of type H_3PO_n and HPO_n^{-1}				Acids of type $H_4P_2O_n$		
	Formula		Name	Salts	Formula	Name	Salts
	Ortho-	Meta-					
+1	H_3PO_2		phosphinic acid, hypophosphorous acid, phosphoric(I) acid	hypophosphites, phosphates(I)			
+2					$H_4P_2O_4$	hypodiphosphonic acid, diphosphoric(II) acid	hypodiphosphites, diphosphates(II)
+3	H_3PO_3	HPO_2	phosphonic acid, phosphorous acid, phosphoric(III) acid	phosphites, phosphates(III)	$H_4P_2O_5$	diphosphonic acid, diphosphoric(III) acid	diphosphites, diphosphates(III)
+4					$H_4P_2O_6$	hypodiphosphoric acid, diphosphoric(IV) acid	hypodiphosphates, diphosphates(IV)
+5	H_3PO_4	HPO_3	phosphoric acid, phosphoric(V) acid	phosphates, phosphates(V)	$H_4P_2O_7$	diphosphoric acid, pyrophosphoric acid, diphosphoric(V) acid	diphosphates, diphosphates(V)

1.3.1. Phosphinic Acid

Phosphinic acid [*6303-21-5*], hypophosphorous acid [*14332-09-3*], H_3PO_2, M_r 66.0, *mp* 26.5 °C, forms colorless leaflets. It is obtained by reaction of its salts with sulfuric acid. The salts are usually prepared by heating phosphorus with alkali or alkaline earth metal hydroxides, whereby a disproportionation reaction occurs. On an industrial scale, calcium hydroxide is used:

$$2\,P_4 + 3\,Ca(OH)_2 + 6\,H_2O \rightarrow 2\,PH_3 + 3\,Ca(H_2PO_2)_2$$

$$Ca(H_2PO_2)_2 + H_2SO_4 \rightarrow CaSO_4 + 2\,H_3PO_2$$

On evaporating the aqueous solution, the phosphinic acid crystallizes with a lamellar structure. Oxidation of PH_3 by iodine in aqueous solution also produces phosphinic acid.

$$PH_3 + 2\,I_2 + 2\,H_2O \rightarrow H_3PO_2 + 4\,HI$$

Phosphinic acid forms esters with two tautomeric structures.

Phosphinic acid is a considerably stronger reducing agent than phosphonic acid, being converted firstly into phosphonic and then phosphoric acid. On heating to 130 – 200 °C, it disproportionates into phosphine and phosphoric acid.

$$2\,H_3PO_2 \rightarrow PH_3 + H_3PO_4$$

Both the hydrogen atoms bound to the phosphorus in phosphinic acid can be replaced by alkyl groups to give mono- and dialkyl phosphinic acids.

Phosphinic acid can be distinguished from phosphonic acid by its reaction with copper sulfate solution. It reduces $CuSO_4$ not just to metallic copper, but to copper hydride CuH.

All salts of phosphinic acid, MH_2PO_2, are very soluble in water.

Hypodiphosphoric acid, $H_4P_2O_6$, can be prepared by first oxidizing red phosphorus with H_2O_2 or other oxidizing agents in strongly alkaline solution to form $Na_2H_2P_2O_6$ or $BaH_2P_2O_6$. Good yields are obtained when the red phosphorus is oxidized at 12 – 15 °C by $NaClO_3$ [16]. The free acid is obtained by reacting the salts with sulfuric acid. On evaporation, the acid is obtained as the hydrate $H_4P_2O_6 \cdot H_2O$ (*mp* 62 °C). The anhydrous compound $H_4P_2O_6$ (*mp* 55 °C) can be obtained by vacuum drying over phosphorus pentoxide. However, diphosphoric(IV) acid, $(HO)_2OP{-}PO(OH)_2$, is unstable, and gradually changes into the isomeric diphosphoric (III,V) acid, $(HO)_2P{-}O{-}PO(OH)_2$.

1.3.2. Phosphonic Acid

Phosphonic acid [*13598-36-2*], phosphorous acid [*10294-56-1*], H_3PO_3, M_r 82.00, was obtained as a mixture with other oxoacids by the oxidation of white phosphorus by moist air in 1777 by Le Sage. In the anhydrous state, it forms colorless crystals, ϱ 1.65 g/cm^3, *mp* 70.1 °C, which are very soluble in water. It is a dibasic acid, and so forms both hydrogenphosphites and phosphites.

Phosphonic acid can be obtained by dissolving P_4O_6 in cold water, or by reaction of its calcium salt with sulfuric acid. It is now produced industrially by spraying phosphorus trichloride with water vapor into a hot reaction zone where the excess water and the hydrochloric acid formed are evaporated off [17].

$$PCl_3 + 3\,H_2O \rightarrow H_3PO_3 + 3\,HCl$$

This reaction has been operated as a continuous process by Hoechst for many years. In a Monsanto process [18], phosphonic acid is produced by indirect electrolytic oxidation of elemental phosphorus.

The trialkyl derivatives (esters) exist in two forms: $P(OR)_3$ can be converted to the more stable form $OPR(OR)_2$.

Phosphonic acid is a strong reducing agent. On heating in the dry state, it disproportionates to form phosphoric acid and phosphine.

The salts of phosphonic acid are not oxidized in air, whereas the free acid is slowly converted into orthophosphoric acid.

Phosphonic acid is used as the starting material for preparing basic lead phosphite, which is added to chlorine-containing plastics (e.g., PVC) to stabilize them against light and heat. Its principal use is in the synthesis of various phosphorus(III) compounds [19].

Phosphonic acid is supplied in flake form in polyethylene-lined paper sacks. The H_3PO_3 content of the commercial product is ca. 98.5 % (0.5 % H_3PO_4, the rest water).

2. Phosphorus – Halogen Compounds

Of the many compounds of phosphorus with the halogens, only those of the type PX_3, PX_5, POX_3, and PSX_3 (X = Cl or Br) are of industrial and economic importance. The corresponding fluorine, iodine, and polymeric halogen compounds are of only academic interest. The most important phosphorus – halogen compound is phosphorus trichloride, for which world production capacity in 1989 was estimated at >300 000 t. All the industrially important derivatives such as phosphorus pentachloride, phosphoryl chloride, and thiophosphoryl chloride are produced from phosphorus trichloride. Some figures for world consumption in 1989 are: PCl_3, 168×10^3 t; PCl_5, 4×10^3 t; $POCl_3$, 82×10^3 t. The stability of the tri- and pentahalides decreases with increasing atomic mass of the halogen atom. All the phosphorus halides are extremely sensitive to atmospheric moisture. They react very vigorously with water, the halogens being replaced by OH groups. Hydrogen halides, phosphonic and phosphoric acids, and sometimes phosphine (spontaneously flammable) are formed. A large excess of water must be used when dealing with spillages [20]. The phosphorus chlorides are neither flammable nor explosive.

Properties. Some physical properties of the most important phosphorus halides are given in Table 2 [21–23]. Phosphorus trichloride, phosphoryl chloride, and thiophosphoryl chloride are liquids at room temperature; phosphorus pentachloride is a solid. The molecules of the phosphorus trihalides are trigonal pyramidal, with the phosphorus atom at the apex. The structure of the phosphorus pentahalides is a trigonal bipyramid with the phosphorus atom at the center. This is true for phosphorus pentafluoride in all states of aggregation, but for the other pentahalides only when in the gas phase or in solution. Crystalline phosphorus pentachloride and pentabromide are composed of ions, i.e., $(PCl_4)^+$ $(PCl_6)^-$ and $(PBr_4)^+$ Br^-. In addition to the compounds listed in Table 1, the following mixed phosphorus trihalides are known:

	mp	*bp*
PF_2Cl	− 164.8 °C,	− 47.3 °C
$PFCl_2$	− 144.0 °C,	+ 13.85 °C
PF_2Br	− 133.8 °C,	− 16.1 °C
$PFBr_2$	− 115.0 °C,	+ 78.4 °C

Table 2. Some physical properties of phosphorus – halogen compounds

Substance	PF_3	PF_5	PCl_3	PCl_5	PBr_3	PBr_5	$POCl_3$	$PSCl_3$

2.1. Phosphorus Tri- and Pentahalides

2.1.1. Phosphorus Trichloride

Phosphorus trichloride [*7719-12-2*], PCl_3, M_r 137.33, was discovered in 1808.

Some physical properties are as follows:

Heat of evaporation		31 kJ/mol
Molar heat capacity		120.9 J mol^{-1} K^{-1}
Vapor pressure:	20 °C	12.97 kPa
	70 °C	85.75 kPa
Viscosity:	0 °C	0.65 cP
	50 °C	0.438 cP

Phosphorus trichloride is a clear, volatile liquid, which is rapidly hydrolyzed by water with evolution of heat to form phosphonic acid $HP(O)(OH)_2$, and hydrochloric acid. Phosphorus trichloride has an irritant effect on the mucous membranes. It is soluble in benzene, chloroform, carbon tetrachloride, and diethyl ether, and is miscible with phosphoryl chloride. Addition of chlorine, oxygen, and sulfur to the phosphorus electron lone pair occurs readily, giving phosphorus(V) compounds.

Production. Phosphorus trichloride is formed by the combustion of phosphorus in a dry stream of chlorine.

$$P_4 + 6\,Cl_2 \rightarrow 4\,PCl_3 \quad \Delta H = -1276\,\text{kJ/mol}$$

In a Hoechst continuous process, molten white phosphorus and gaseous chlorine react in previously produced phosphorus trichloride. The formation of phosphorus pentachloride is prevented by the presence of a small excess of phosphorus. The heat of reaction, ca. 10 times the heat of evaporation, keeps the system at its boiling point, and the phosphorus trichloride distills off. The vapors are fractionated as reflux takes place, and the PCl_3 condenses in air-cooled condensers. The rate of removal of PCl_3 (i.e. the production rate) is equivalent to the feed rate of phosphorus and chlorine. The process is controlled by the boiling temperature, which is determined by the phosphorus content [24]. The rate of chlorine flow is fixed, and the phosphorus feed rate is adjusted manually. The phosphorus trichloride produced contains no free phosphorus and needs no further treatment. The impurities from the phosphorus remain in the reactor, and are removed periodically, i.e., the phosphorus trichloride is completely driven off by distillation, and the tarry mass remaining is removed and can be burnt.

In another process, liquid phosphorus and gaseous chlorine are reacted in a combustion chamber to form phosphorus trichloride. The product is then distilled [25].

The commercial product contains ca. 99 % phosphorus trichloride, the main impurity being phosphoryl chloride. The boiling range is 74.5 – 76.5 °C.

Phosphorus trichloride is transported in steel drums or tank cars, U.N. no. 1809, RID/ADR/IMO Class 8, Section 11 a. Road transport is in tank trucks, for which pure nickel has good corrosion resistance.

Uses. Phosphorus trichloride is mainly used for the manufacture of phosphoryl chloride, phosphorus pentachloride, thiophosphoryl chloride, and phosphonic acid. It is the starting material in the production of organophosphorus

compounds. Phosphite esters are formed by reaction with alcohols and phenols. Phosphorus trichloride is an important intermediate in the production of phosphate ester insecticides. Hydrocarbons, particularly alkenes, react with phosphorus trichloride to form phosphinic and phosphonic acids (see → Phosphorus Compounds, Organic). In organic chemistry, phosphorus trichloride is used as a chlorinating agent and catalyst, e.g., fatty acid chlorides are obtained by the reaction of fatty acids with phosphorus trichloride, phosphonic acid being the byproduct [26].

2.1.2. Phosphorus Pentachloride

Phosphorus pentachloride [*10026-13-8*], PCl_5, M_r 208.23, is a white, crystalline mass when pure. It fumes in air and has a strong, pungent odor. It was discovered in 1810 by Davy. Phosphorus pentachloride has a vapor pressure of 1.6 Pa at 20 °C, and is 40 % dissociated into phosphorus trichloride and chlorine at 180 °C, 80 % at 250 °C, and in the vapor phase at 300 °C is fully dissociated.

Production. Phosphorus pentachloride can be prepared by the reaction of excess chlorine with phosphorus trichloride.

$$PCl_3 + Cl_2 \rightarrow PCl_5 \quad \Delta H = -125\ \text{kJ/mol}$$

Small quantities of phosphorus pentachloride can be prepared by the reaction of chlorine with phosphorus trichloride dissolved in carbon tetrachloride. The phosphorus pentachloride crystallizes out and is purified by vacuum distillation. Industrial batch manufacture is performed by passing chlorine into phosphorus trichloride. The heat of reaction is removed by cooling the vessel and by the latent heat of evaporation. With careful reaction control in a stirred stainless steel reactor, a granular, free-flowing product is obtained. This can be packed and transported in plastic containers, U.N. no. 1806, RID/ADR Class 8, Section 11 a, IMO Class 8. When working with phosphorus pentachloride, it is important to keep it cool, to keep the storage time short, and to prevent contact with moisture.

Uses. Phosphorus pentachloride is used in organic chemistry as a mild chlorinating agent. Two of the three chlorine atoms are easily split off. It is used in the pharmaceutical industry in the manufacture of penicillin and cephalosporin antibiotics. Phosphonic acids are produced on reaction with alkenes. In aluminum metallurgy, it is used as a grain refiner for Al – Si alloys. With compounds containing carboxyl groups, phosphorus pentachloride reacts to form phosphoryl chloride and the corresponding acid chlorides, with liberation of hydrogen chloride.

2.1.3. Phosphorus Tribromide

Phosphorus tribromide [*7789-60-8*], PBr_3, M_r 270.7, U.N. no. 1808, is a strongly corrosive liquid which fumes in air. All methods of preparation start from the elements. The reaction with white phosphorus is very violent, and the phosphorus is therefore dissolved in carbon disulfide or submerged in benzene. Phosphorus tribromide is mainly used as a brominating agent in organic chemistry.

2.1.4. Phosphorus Fluorides

Phosphorus trifluoride [*7783-55-3*], PF_3, M_r 87.96, is a colorless gas which does not fume in air when pure. It is not prepared from the elements but by exchange reactions between other phosphorus and fluorine compounds, e.g., by dropwise addition of arsenic trifluoride to phosphorus trichloride. This forms gaseous phosphorus trifluoride, which is washed with water, dried, and isolated by freezing. Other methods of preparation are the reaction of copper phosphide with lead fluoride or of phosphorus tribromide with zinc fluoride. Phosphorus trifluoride has little commercial importance. Reaction with hydrocarbons produces fluorocarbons [27].

Phosphorus pentafluoride [*7647-19-0*], PF_5, M_r 125.96, U.N. no. 2198, is a colorless gas, which has an unpleasant odor and fumes in air. It is the most stable pentahalide of phosphorus, and is prepared in a similar way to phosphorus trifluoride, i.e., by double decomposition, for example as follows:

$$3\,PCl_5 + 5\,AsF_3 \rightarrow 3\,PF_5 + 5\,AsCl_3$$

Other methods of preparation include the reaction of phosphorus trichloride with fluorine [28], or with chlorine and calcium fluoride [29]. The gaseous product is purified by passing it over an alkali metal to remove the residual chlorides. Phosphorus pentafluoride is a relatively mild fluorinating agent of very minor industrial importance.

2.2. Phosphoryl and Thiophosphoryl Halides

In addition to the compounds thiophosphoryl fluoride, phosphoryl chloride, and thiophosphoryl chloride, many mixed substituted phosphoryl and thiophosphoryl halides have been described, e.g., POF_2Cl (*mp* −96.4 °C, *bp* +3.1 °C), $POFCl_2$ (*mp* −80.1 °C, *bp* +52.9 °C), POFClBr (*bp* +79 °C), and PSFClBr.

Condensed compounds such as pyrophosphoryl chloride $P_2O_3Cl_4$, pyrophosphoryl fluoride $P_2O_3F_4$, and tetraphosphoryl decachloride $P_4O_5Cl_{10}$ are also known, all of which contain P−O−P groups and should be regarded as halides of condensed phosphoric acids.

Some properties of the phosphoryl and thiophosphoryl halides are given in Table 3. They are all colorless at room temperature.

All these compounds are very reactive, the reactivity increasing from the fluorides to the iodides. Like the binary halides, they are sensitive to moisture and hydrolyze to give the corresponding phosphorus acids. In the phosphoryl and thiophosphoryl halides, the phosphorus atom is tetrahedral.

2.2.1. Phosphoryl Chloride

Phosphoryl chloride [*10025-87-3*], $POCl_3$, M_r 153.33, was discovered in 1847 by WURTZ. It is a colorless liquid which fumes in air and has a pungent odor. It is obtained by oxidizing phosphorus trichloride with air or oxygen.

$$PCl_3 + {}^{1}\!/_{2}\,O_2 \rightarrow POCl_3 \quad \Delta H = -279.5\,\text{kJ/mol}$$

It can be produced industrially either batchwise or in a continuous process. A finely divided stream of oxygen is reacted with phosphorus trichloride until the freezing point of the product is 1 °C. The reaction is accelerated by carrying it out under pressure. The presence of orthophosphoric acid has a catalytic effect, but traces of metallic impurities such as copper and cobalt, or of sulfur compounds, decrease the reaction rate. In a Hoechst process, phosphorus trichloride and oxygen are passed in cocurrent through a stainless steel water-cooled packed column. The oxidation process, i.e., the uptake of oxygen, can be followed by the characteristic temperature changes. The first product, which leaves the column at a maximum temperature of 35 °C, has a freezing point of ca. 0.9 °C, and is taken from the top of the column into a second column where it is again treated with oxygen. This procedure avoids large temperature increases. The excess oxygen leaving the plant passes through a cold trap where entrained phosphoryl chloride is condensed out and recovered. The off-gas is then scrubbed with water. Commercial phosphoryl chloride contains ca. 99.5 % $POCl_3$ and traces of phosphorus trichloride.

It is transported in drums with polyethylene liners, and in lead-lined or stainless steel heated tank cars or tanker trucks (U.N. no. 1810, Class 8, Section 12).

Uses. Phosphoryl chloride is used on a large scale to produce phosphate esters by reaction with alcohols and phenols. It is an ionizing solvent, dissociating to a small extent according to:

$$POCl_3 \rightleftharpoons POCl_2^+ + Cl^-$$

2.2.2. Thiophosphoryl Chloride

Thiophosphoryl chloride [*3982-91-0*], $PSCl_3$, M_r 169.51, U.N. no. 1837, is a colorless liquid with an unpleasant odor. It is hydrolyzed by water to form hydrogen sulfide, orthophosphoric acid, and hydrochloric acid. It is soluble in benzene and carbon disulfide.

Production. Thiophosphoryl chloride is prepared by the direct reaction of excess sulfur with phosphorus trichloride at ca. 180 °C, either as a batch process in an autoclave or under reflux. The product is purified by distillation. Yields are up to 98 %. The reaction is accelerated and the

reaction temperature reduced by the addition of catalysts such as halides of aluminum [30] or iron [31], or disulfur dichloride [32]. Alternatively, thiophosphoryl chloride can be prepared by the reaction of phosphorus pentachloride with phosphorus pentasulfide, or of phosphorus pentachloride with antimony trisulfide.

Figure 1. Structure of the phosphorus sulfides

Uses. Thiophosphoryl chloride is used to introduce the P−S group into organic compounds. Thiophosphate esters are prepared by reacting thiophosphoryl chloride with alcohols, sodium alkoxides, phenols, or trialkyl phosphites. Inorganic thiophosphates are produced by the alkaline hydrolysis of thiophosphoryl chloride.

3. Phosphorus Sulfides

The sulfides of phosphorus form a series of compounds with the general formula P_4S_n ($n = 2-10$) [33]. They may be formally derived by the successive introduction of sulfur atoms into the P−P bonds of the P_4 tetrahedron, and by addition of sulfur atoms to the P atoms. Further addition of sulfur to P_4S_{10} leads to incompletely characterized substances containing $P-(S)_n-P$ groups [34], [35]. The structures of some phosphorus sulfides are shown in Figure 1. Thermochemical data and the phase diagram of the phosphorus – sulfur system are given in [36–38]. The reaction of P_4S_{10} with P_4O_{10} gives mixed phosphorus oxide sulfides [39].

Properties. Table 4 lists physical properties of some phosphorus sulfides. They are yellow, crystalline substances with an odor of hydrogen sulfide due to hydrolysis when handled in air. With the exception of P_4S_3, which has only a slight tendency to hydrolyze, all the phosphorus sulfides decompose relatively rapidly in the presence of water, acids, or alkalies. When they are melted or vaporized, decomposition takes place. P_4S_3 is the only phosphorus sulfide that can be melted and evaporated unchanged. All phosphorus sulfides are flammable. The ignition temperature of P_4S_3 in air is only ca. 100 °C; that of P_4S_{10} is ca. 270 °C. There is a danger of dust explosions, particularly when grinding or on filling or discharging the material. Dust – air mixtures containing $> 3\,\%$ oxygen and > 50 g/m^3 P_4S_{10} (particle size < 0.07 mm) are explosive. Containers and items of plant should be filled with an inert gas (nitrogen), and all metallic parts should be earthed.

[a] Decomposition.
[b] Grams per 100 g carbon disulfide.

Preparation. The simplest method of preparing phosphorus sulfides is by heating stoichiometric mixtures of the elements to temperatures above their melting points, followed by cooling. The compounds P_4S_3, P_4S_7, P_4S_9, and P_4S_{10} can be prepared in this way. Either white or red phosphorus can be used. As a rule, pure products are not obtained, and further treatment or purification is necessary. When the reactions are carried out in organic solvents (usually carbon disulfide), phosphorus sulfides can be produced that are not obtainable by the fusion method on account of decomposition reactions. These include, P_4S_5, synthesized by reaction of P_4S_3 with sulfur, and β-P_4S_5, obtained from P_4S_7 by removal of sulfur with triphenylphosphine.

Production. Industrial production of *tetraphosphorus decasulfide*, P_4S_{10} (known in industry as phosphorus pentasulfide or "pentasulfide"), are continuous processes that use white phosphorus and sulfur as starting materials. Molten phosphorus and sulfur are fed into a vessel containing liquid phosphorus pentasulfide at 280–515 °C. Some producers purify the crude liquid product by distillation [40], [41], the heat of evaporation being provided by the heat of reaction. However, the required purity of the final product can also be attained by using specially purified starting materials [42]. Organic impurities are removed from white phosphorus by treatment with concentrated sulfuric acid, and the purified phosphorus is reacted with highpurity sulfur. In this way, distillation of the pentasulfide can be dispensed with, and the liquid reaction product can be fed directly to cooling rollers and then ground.

If the molten product is cooled slowly, fully crystalline phosphorus pentasulfide of low reactivity is obtained, whereas the product obtained by quenching on a cooling roller contains amorphous material and is very reactive. Material of lower reactivity can be prepared from this reactive form by a tempering process [43]. The reactivity of the pentasulfide is an important product characteristic, which is of particular importance for further processing. The reactivity is measured by a simple alcoholysis test, in which the temperature increase due to the heat of reaction is measured when a sample of pentasulfide is reacted with an alcohol (e.g., 2-ethylhexanol). Commercial-quality phosphorus pentasulfide does not consist of a single phase, although the analysis corresponds almost exactly to the stoichiometric compound P_4S_{10}. In addition to the main component P_4S_{10}, a proportion of P_4S_9 is present, and some uncharacterized polymers containing $P-(S)_n-P$ groups [35], [44].

Tetraphosphorus trisulfide [*1314-85-8*], phosphorus sesquisulfide, P_4S_3, is produced by adding phosphorus to liquid sulfur, and distilling the product.

Transportation. Phosphorus pentasulfide is transported in iron drums or aluminum containers. It is a flammable solid with the following transport classifications:

Road∗:	ADR (GGVS) Class 4.1, Rn 2401, Section 8
Rail∗:	RID (GGVE) Class 4.1, Rn 401, Section 8
Sea:	IMDG-Code (GGVSee) Class 4.1, U.N. no. 1340, Packing Group II
Air:	IATA Class 4.3, U.N. no. 1340, Packing Group II

∗ Will presumably be changed by the end of 1992 to Class 4.3, Section 20 b.

Uses. Phosphorus pentasulfide is mostly reacted with alcohols and phenols to form dialkyl

and diaryl dithiophosphate esters. These are important intermediates in the manufacture of insecticides, lubricating oil additives, and flotation agents (→ Phosphorus Compounds, Organic). It is also used to a very small extent in organic chemistry as a sulfurizing reagent.

Tetraphosphorus trisulfide, P_4S_3, is used in the match industry in the manufacture of strike-anywhere matches (→ Matches).

[a] cub = cubic, tet = tetragonal, hex = hexagonal, tri = trigonal, ort = orthorhombic, mon = monoclinic.

Economic Aspects. Tetraphosphorus decasulfide is economically important, as is tetraphosphorus trisulfide, though to a much lesser extent. None of the other phosphorus sulfides are of economic importance. In 1989, world capacity for phosphorus pentasulfide was estimated to be a little over 200 000 t, and the actual production ca. 150 000 t. Consumption was divided up as follows: ca. 50 % for lubricating oil additives, ca. 45 % for insecticides, and ca. 5 % for other uses, mainly as flotation agents.

Tetraphosphorus trisulfide is of comparatively minor importance; world production in 1989 was 150 – 200 t.

4. Phosphides

Phosphides are compounds of phosphorus with elements of lower electronegativity. Most metals form compounds with phosphorus. These are mainly binary metal phosphides, but a few are ternary. Some nonmetals and semimetals such as boron or silicon are also known to form phosphides. In total, well over 500 different phosphides have been described, and in many instances have been characterized by determining their crystal structure [45], [46]. Physical data for some phosphides are given in Table 5.

The phosphides may be classified in various ways. The usual classification is based on the stoichiometry, i.e., into metal-rich phosphides (M/P > 1), monophosphides (M/P = 1), and phosphorus-rich phosphides (M/P < 1). Metal-rich phosphides are usually hard, brittle substances with a metallic luster. They possess relatively high thermal and electrical conductivity and are thermally stable and very unreactive. They are stable towards water and dilute acids. Some are decomposed only by molten alkali. The industrial products are often regarded as metal–phosphorus alloys. The monophosphides have similar properties to the metal-rich phosphides. For example, those of the elements of group 3 have marked semiconductor properties. Phosphorus-rich phosphides typically have lower melting points and lower thermal stabilities than the monophosphides or the metal-rich phosphides. With increasing phosphorus content, the phosphorus atoms increasingly cross-link, forming polyphosphide anions. In some of these polyphosphides, structural elements typical of violet (Hittorf's) phosphorus appear. Alkali metals, alkaline earth metals, and lanthanides form phosphides with largely ionic character. A typical reaction of these salt-like compounds is their smooth hydrolysis to give PH_3.

Production. The simplest method of production is direct combination of the elements at elevated temperature. White, red, or gaseous phosphorus can be used. Some phosphides can be prepared by reaction of phosphine with metals or their salts. Metallic phosphides can also be prepared by the electrothermal reduction of metal oxides in the presence of carbon and phosphates. Ferrophosphorus is produced in this way from the iron-containing impurities present in the phosphate rock used in the production of phosphorus (→ Phosphorus).

Uses. Phosphine, produced in large quantities by hydrolyzing metal phosphides, is used in pest control (see Chap. 5). The most important compounds used are aluminum phosphide AlP (Phostoxin, Degesch), and magnesium phosphide Mg_3P_2 (Magtoxin, Degesch). Compared with pure PH_3, these have the advantage of being much safer to use. The products are protected against uncontrollably rapid hydrolysis, such as could occur by accidental contact with water, by coating their surfaces with hydrophobic substances such as paraffin or metal stearates. By mixing the material with ammonium carbamate, which produces ammonia and carbon dioxide on decomposition, the possible spontaneous ignition of the PH_3 produced is prevented [47]. The annual world production of AlP and Mg_3P_2 together amounts to ca. 3000 t. Aluminum phosphide and calcium phosphide (Polytanol) Ca_3P_2 are used as rodenticides, especially for voles. Zinc phosphide Zn_3P_2 is used to prepare poison bait for rodent control.

Gallium phosphide GaP, indium phosphide InP, and the mixed crystals with their respective arsenides, are important semiconductors, e.g., in the manufacture of light-emitting diodes (→ Electroluminescent Materials and Devices).

The phosphides of iron, copper, and tin are used in metallurgical processes. Iron phosphide (ferrophosphorus [*8049-19-2*]) is used in by far the largest quantities. It has an average phosphorus content of 20 – 27 %, so that the principal constituent is diiron phosphide Fe_2P (phosphorus content 21.7 %). Ferrophosphorus is produced as a byproduct in the manufacture of yellow phosphorus. The production rate therefore directly depends on the phosphorus production rate and on the iron content of the phosphate rock. World production is ca. 50 000 t. The main application is in the foundry and steel industries. For certain applications, the phosphorus content of cast iron and steel must be increased by the addition of ferrophosphorus. The phosphorus content (up to 1.5 %) improves the flow properties of cast iron and increases its wear resistance. When manufacturing free-cutting steel, the presence of a small percentage of phosphorus (up to 0.3 %) improves machinability.

The phosphides of copper and tin are mainly used as deoxidants in the production of the corresponding metals (→ Copper Alloys, Chap. 2.1.) and as constituents of phosphor bronzes (→ Copper Alloys, Chap. 6.1.) and hard solders (brazing materials). The usual commercial products are copper – phosphorus alloys with 10 or 15 % P (principle constituent Cu_3P) and tin –phosphorus alloys containing 5 % P. Microcrystalline nickel phosphide Ni_3P is present in the nickel layer produced by the electrodeless deposition of nickel (→ Electrochemical and Chemical Deposition).

5. Phosphorus – Hydrogen Compounds

Phosphorus and hydrogen form a large number of compounds, which have been characterized mainly by spectroscopic methods [48]. The known hydrides of phosphorus are exceeded in number only by those of carbon. However, the only phosphorus hydride that is of economic importance is phosphine [49].

Phosphine [*7803-51-2*], phosphane, PH_3 is a colorless, very poisonous gas (*mp* −134 °C; *bp* − 88 °C; vapor pressure 3.6 MPa at 20 °C). Above 375 °C, it decomposes into the elements. Phosphine – air mixtures are explosive over a wide range. The lower explosion limit is 1.6 %, and the upper limit is close to 100 % [50]. Pure phosphine should presumably therefore be regarded as spontaneously flammable like phosphine that contains P_2H_4 as an impurity. Although phosphine has a garliclike odor, the threshold of detection can exceed several hundred ppm if the gas is very pure. The characteristic odor of acetylene is due to phosphine, produced when the acetylene is generated from calcium carbide that contains calcium phosphide

as an impurity. With strong acids, phosphine forms phosphonium salts; e.g., with hydrogen iodide, phosphonium iodide [*12125-09-6*], PH_4I, is formed, from which pure phosphine may be liberated by adding water or solutions of alkalimetal hydroxides.

Production. Phosphine can be synthesized by a number of different reactions [49]. On the laboratory scale, it may be prepared simply by the hydrolysis of metal phosphides or phosphonium salts. The two most common industrial methods are based on disproportionation reactions of elemental phosphorus catalyzed by alkali or acids. A well-known example is the reaction of white phosphorus with sodium hydroxide solution, which is used to produce both phosphine and sodium hypophosphite [*7681-53-0*], NaH_2PO_2 (sodium phosphinite).

$$P_4 + 3\,NaOH + 3\,H_2O \rightarrow PH_3 + 3\,NaH_2PO_2$$

In sodium hypophosphite production plants, the phosphine byproduct is usually burnt off. In the presence of alcohols, the reaction may be controlled such that the product formed in addition to phosphine is almost entirely sodium phosphite Na_2HPO_3 [51]. At the same time, the maximum yield based on the amount of phosphorus used increases from 25 % to 50 %. In acid-catalyzed disproportionation, white phosphorus is converted into phosphine and phosphoric acid at ca. 280 °C, red phosphorus being formed as an intermediate [52].

$$2\,P_4 + 12\,H_2O \rightarrow 5\,PH_3 + 3\,H_3PO_4$$

This reaction gives the highest yield of PH_3 based on the amount of phosphorus used (theoretical yield 62.5 %). Due to the high reaction temperature and the corrosiveness of the medium, the reactor must be made of graphite.

Uses. World production of phosphine is ca. 1500 t/a. The phosphine is mostly used captively as a starting material in the production of organophosphorus compounds, mainly by addition of aldehydes or alkenes to the P–H bonds (→ Phosphorus Compounds, Organic). Phosphine is also used for pest control (see Chap. 4) where foodstuffs and animal feeds are stored. Almost all dry products of this type are suitable for gassing with phosphine without any harmful effects on such properties as smell, taste, and appearance. The main area of use is in gassing grain silos. In the semiconductor industry, specially purified phosphine (arsine-free in particular) is used as a dopant.

Polyphosphanes. The simplest polyphosphane is diphosphane [*13445-50-6*], P_2H_4, a spontaneously flammable liquid with an unpleasant smell (*bp* 63 °C). Diphosphane is formed together with phosphine in the hydrolysis of calcium phosphide Ca_3P_2. Diphosphane belongs to the straight-chain phosphanes. It is part of a homologous series with the general formula P_nH_{n+2}, in which the higher members have very low thermal stability. Thermal decomposition of diphosphane yields a large number of different polyphosphanes, some of which have been characterized by means of mass and NMR spectroscopy [48]. In addition to the straight-chain structures, monocyclic and, to a greater extent, polycyclic structures exist. The individual compounds can be allocated to various homologous series with the general fomulae P_nH_n (cyclic compounds), P_nH_{n-2}, and P_nH_{n-4} to P_nH_{n-18} (polycyclic compounds). Polyphosphanes that have been prepared in the pure state are diphosphane; triphosphane(5) [*13597-70-1*], P_3H_5; pentaphosphane(5) [*6798-45-4*], P_5H_5; and heptaphosphane(3) [*51273-53-1*], P_7H_3.

6. Phosphorus – Nitrogen Compounds

Although a large number of inorganic phosphorus – nitrogen compounds exist, hardly any of these are of industrial importance, with the exception of the phosphazenes. Many compounds that contain a P–N bond can be regarded as formal derivatives of the oxoacids of phosphorus, in which P–OH or P=O groups are replaced by the isoelectronic $P-NH_2$ or P=NH groups. The phosphorus nitrides with various P–N ratios described in the literature are mostly amorphous substances. Only triphosphorus pentanitride [*12136-91-3*], P_3N_5, is known in the crystalline state. It is formed by the thermal decomposition of the product of the reaction between PCl_5 and NH_3. Phospham [*33849-97-7*], phosphorus nitride imide $[PN(NH)]_x$ is the intermediate product, which is converted at 500 °C to P_3N_5, a white, insoluble powder that can be

used for flameproofing cellulose fibers [53] or wood surfaces [54]. The halogenophosphazenes (phosphonitrilic halides), especially the chlorine compounds, are of greater importance [55]. Phosphazene is a general term for unsaturated phosphorus – nitrogen compounds with alternating P and N atoms. The halogenophosphazenes form a large group of oligomeric and polymeric compounds with both cyclic and linear structures, with the general formula $(PNX_2)_n$ ($n \geq 3$, X = halogen).

The chlorocyclophosphazenes are white, crystalline solids, while the short-chain linèar compounds are oily liquids. The simplest compound, which has been known for many years, is hexachlorocyclotriphosphazene [*940-71-6*], $(PNCl_2)_3$ (*mp* 114 °C, *bp* 256 °C, ϱ 1.99 g/cm^3), which is produced on an industrial scale as the starting material for the manufacture of organosubstituted polyphosphazenes. It forms an almost planar six-membered ring with equal P–N bond lengths. The monomeric $PNCl_2$ (phosphorus dichloride nitride) is unknown.

Figure 2. Synthesis of polyorganophosphazenes

The simple chlorocyclophosphazenes polymerize on heating to 250 – 350 °C to form rubber-like products ("inorganic rubber"). These are cross-linked polymers which are insoluble in organic solvents and have no direct application on account of their marked tendency to hydrolyze. However, hydrolysis can be prevented if the halogen atoms are completely replaced by organic groups. Complete substitution can only be achieved if the only polymer present is linear poly(dichlorophosphazene), [*25034-79-1*] $(PNCl_2)_n$ ($n \leq 15\,000$) [56]. This substance, not being cross-linked, can be dissolved in organic solvents such as toluene, and then converted into chlorine-free products by reaction with alkoxides, phenoxides, or amines (Fig. 2). The polyorganophosphazenes produced in this way are hydrolytically stable elastomers with a wide range of possible applications [55], [57–59], (→ Inorganic Polymers, Chap. 4.).

Production. The starting material for the production of chlorophosphazenes is phosphorus pentachloride, which is reacted with finely divided ammonium chloride in an inert organic solvent such as chlorobenzene or 1,1,2,2-tetrachloroethane at elevated temperature. Catalysts are usually added, e.g., metal salts or quinoline derivatives [60].

$$n\,PCl_5 + n\,NH_4Cl \rightarrow (PNCl_2)_n + 4\,n\,HCl$$

In addition to the trimer, the crude reaction product contains higher cyclic oligomers and a number of linear phosphazenes. The isolation of the desired trimer is usually carried out by washing with water and vacuum distillation [61]. The trimer can be polymerized either in the molten state or in solution. Excess PCl_5 or traces of water and other impurities can impede polymerization and lead to cross-linking reactions. By adding catalysts (mainly Lewis acids such as BCl_3), the temperature required for polymerization can be reduced from 250 – 300 °C to 200 – 220 °C, and the yield increased [62], [63]. These catalysts are assumed to remove a chlorine atom from the phosphazene ring, forming an ionic intermediate compound and thereby initiating polymerization.

Although the cost of the starting materials PCl_5 and NH_4Cl is low, the production cost of pure trimeric chlorophosphazene is relatively high due to the high cost of purification. This means that industrial applications are limited to areas in which the outstanding material properties of the end products are of overriding importance (→ Inorganic Polymers, Chap. 4.).

7. Toxicology

Phosphorus Oxides. In contrast to the oxides of arsenic, the phosphorus oxides P_4O_6 and P_4O_{10} do not possess any specific toxicity [64]. Phosphorus pentoxide is irritating to corrosive to the skin and the mucous membranes, respectively [65]. The MAK value for P_4O_{10} is 1 mg/m^3 [66].

Phosphorus Halides. The phosphorus halides possess a local irritative or corrosive effect, since they form hydrogen halides with water. A detailed description of the toxicological data on phosphorus trichloride and phosphoryl chloride is given in [67].

On contact with moisture, *phosphorus trichloride* is hydrolyzed in an exothermic reaction forming phosphonic acid and hydrogen chloride. Therefore, it is strongly irritating to the skin, eyes, and respiratory tract. Severe corrosion of the skin and mucous membranes may occur upon contact with liquid PCl_3. Irritation is five to six times stronger than would be expected from the hydrochloric acid formed. Due to the high solubility in water, the irritation is highest in the upper respiratory tract. Therefore, the main symptoms consist of irritation of the eyes, throat, and trachea, lacrimation, and coughing. Upon inhalation of higher concentrations, injury of the deeper regions of the lung, and formation of a toxic pulmonary edema can occur. Upon chronic exposure to lower concentrations, cough, dyspnea, and bronchitis have been described. In humans, systemic toxic effects have not been observed till now. In rats, the LC_{50} for a 4-h exposure is 590 mg/m^3 [67]. The MAK value is 3 mg/m^3 [66]; the TLV-TWA value is 1.1 mg/m^3 [68].

Phosphoryl chloride hydrolyzes slowly but exothermically to give phosphoric acid and hydrogen chloride. Therefore, phosphoryl chloride has primarily an irritant action, whereby deeper penetration into the respiratory tract is possible due to the delayed hydrolysis. Often, no complaints are felt in the beginning; only after a latent period of several hours does damage to the deeper respiratory tract occur. This is often of an irreversible nature. For this reason, $POCl_3$ is regarded toxicologically as the most dangerous of the phosphorus chlorides. Characteristic of the inhalative poisoning of humans is the serious state of the lungs, which is in contrast to the relatively good general condition of the affected person. The after-effects of poisoning in those who survive consist frequently of obstructive respiratory tract diseases. Skin contact with liquid phosphoryl chloride can lead to acid burns. The 4-h LC_{50} value in rats is 310 mg/m^3 [67]. The MAK value is 1 mg/m^3 [66], and the TLV-TWA value, 0.63 mg/m^3 [68].

For *phosphorus pentachloride*, whose vapors are similarly strongly irritating to the mucous membranes and respiratory tract [65], the MAK value is 1 mg/m^3 [66] and the TLV-TWA value is 0.85 mg/m^3 [68].

Phosphorus Sulfides. *Tetraphosphorus trisulfide* is not sufficiently volatile to cause an inhalation risk at normal temperatures. In the form of dust or vapor, it irritates the skin, eyes, and respiratory tract. The toxicity is regarded as slight in comparison to white phosphorus [65]. Upon contact with the skin, tetraphosphorus trisulfide can cause eczema [69–72], whereby serious, edematous eczemas of the eyelids and cheeks have been described in some cases. The cutaneous tests were positive to P_4S_3. The oral lethal dose in rabbits is reported to be 100 mg/kg of body weight [73].

Phosphorus pentasulfide, P_4S_{10}, decomposes in the presence of water with the formation of phosphoric acid. Therefore, it acts as an irritant [65]. At the same time, poisonous hydrogen sulfide is formed. In rats, the oral LD_{50} for P_4S_{10} is reported to be 389 mg/kg of body weight [74]. The MAK and TLV-TWA values are both 1 mg/m^3 [66], [68].

Phosphides are decomposed by water or acids with the formation of phosphine, which is the actual cause of phosphide poisoning.

Aluminum, magnesium and zinc phosphides, which are used as rodenticides, react in the gastrointestinal tract with water and hydrochloric acid to give phosphine. In rats, the oral LD_{50} value is 8.7 (AlP), 20.7 (Mg_3P_2, male animals), 10.4 (Mg_3P_2, female animals) and 45 mg/kg (Zn_3P_2) of body weight [75]. In humans, even quantities of 5 g zinc phosphide have caused death, although survival has been reported for doses of 50 g [76]. The relative insensitivity of dogs and cats towards zinc phosphide is attributable to the emetic effect of zinc, which prevents the absorption of larger quantities [77]. In humans, the symptoms of poisoning include exhaustion, nausea, tinnitus aurium, chest complaints, and anxiety. Elementary help, gastric lavage with 0.1 % $KMnO_4$ solution, and symptomatic treatment are recommended as therapy following oral intake [75]. In aluminum phosphide poisoning, treatment consisting of extracorporal hemodialysis as well as sup-

portive cardiovascular-active therapy after gastric lavage with $KMnO_4$ and $MgSO_4$ have been found to be useful [78]. In a long-term study on rats, feeds treated with aluminum phosphide (nominal maximal concentration 30 mg PH_3/kg) caused no toxic or carcinogenic effects [79].

Phosphine. The most important source of poisoning is technical, impure acetylene, which is formed by the action of water on calcium carbide that contains calcium phosphide as an impurity. Phosphine is also formed when ferrosilicon comes into contact with moisture. Phosphine is used as a rodenticide. It is formed from aluminum, magnesium, or zinc phosphide in the presence of moisture and can cause fatal accidents. Quantitatively, poisoning with phosphine does not play any major role today [64], [80].

Phosphine is a highly poisonous gas which acts as a poison in cell metabolism and which can lead to death through internal suffocation. Intake into the organism can occur following inhalation or, after oral intake of phosphides, through the gastrointestinal tract. Phosphine is not absorbed through the skin [67]. Numerous cases of poisoning, sometimes fatal, have been described in humans. The pattern of poisoning resembles poisoning with arsine; however, there are no hemolytic effects. In lower concentrations, symptoms of poisoning may occur after a latent period of several hours. Major symptoms are headache, giddiness, nausea, vomiting, stomach pain, and perhaps diarrhea. After the victim has become unconscious, death usually occurs within 24 – 48 h not only due to pulmonary edema and respiratory paralysis, but also due to cerebral edema and cardiovascular failure. In higher concentrations, sudden death due to pulmonary edema and respiratory paralysis are possible. If the victim survives the poisoning, then damage to the liver and kidneys can appear after a latent period of 24 – 48 h [67], [80].

For humans, concentrations of 400–840 mg/m^3 over a period of 30 – 60 min are extremely dangerous or even lethal, while concentrations of 140 – 260 mg/m^3 are tolerated under these conditions. However, one death has been observed following exposure to 10 mg/m^3 for 6 h [81]. In cats and rats, deaths occur already after acute exposure to 35 mg/m^3. In subacute exposures, death occurs already from concentrations of 7 mg/m^3 onwards [82].

Apparently, a continuous detoxification process occurs in the organism following longer exposure to low phosphine concentrations ($\leq$ 3.5 mg/m^3), so that no chronic cumulative poisoning takes place [82].

Therapy: Symptomatically, treatment of toxic pulmonary edema. A specific therapy for phosphine poisoning is not known [75], [80].

The MAK value is 0.15 mg/m^3 [66]; the TLV-TWA value is 0.42 mg/m^3 [68].

Higher Phosphanes. Diphosphane, a highly poisonous, spontaneously flammable liquid, acts in a similar way to phosphine [80].

1. Introduction

Jürgen Svara and Norbert Weferling

For the purpose of this article, organophosphorus compounds include not only compounds containing a phosphorus – carbon bond, but all compounds of phosphorus with an organic group in the molecule.

Organophosphorus compounds are characterized by an unusually large variety of structures and a wide range of uses. The reason is that phosphorus is able to form stable compounds with a coordination number of 1 to 6, and an oxidation state of – III to + V. Of the wide range of possible compounds, only those of industrial importance are treated here.

The organic chemistry of phosphorus has been described in many reviews. In particular, the chemistry of phosphorus with a low coordination number has been intensively investigated in

recent years [1-9].

2. Phosphines [10]

Jürgen Svara and Norbert Weferling

Phosphines are compounds in which phosphorus has a coordination number of 3 and an oxidation state of – 3. They are derived from phosphine [7803-51-2], PH_3. Successive formal substitution of 1, 2, or 3 hydrogen atoms of PH_3 by alkyl or aryl groups gives primary, secondary, and tertiary phosphines.

2.1. Properties

Under normal conditions, PH_3, methylphosphine CH_3PH_2, trifluoromethylphosphine [420-52-0], CF_3PH_2, and bis(trifluoromethyl)phosphine [460-96-8], $(CF_3)_2PH$, are gases. Most of the known phosphines are colorless liquids at 0.1 MPa and 20 °C, usually immiscible with water, and have a density of 0.8 – 0.85 g/cm^3. *tert*-Alkylphosphines with a chain length > C_{12} tend to crystallize at room temperature. Phosphines that contain a rigid organic group, e.g., 9*H*-9-phosphabicyclononane [13887-02-0], [13396-80-0] are crystalline, as are compounds in which the van der Waals forces resulting from the functional groups leads to formation of crystalline phases [e.g., tris(2-cyanoethyl)phosphine].

Phosphines have an intense and penetrating odor, often described as resembling garlic, even in the ppb range. For phosphine itself, the odor threshold is extremely dependent on the purity of the gas. High-purity PH_3 (5 N), as used in the semiconductor industry, is detectable by smell only when the concentration is at a dangerously toxic level (> 1000 ppm), but when PH_3 is produced by the hydrolysis of AlP or Mg_3P_2 (see also ⟶ Phosphorus Compounds, Inorganic), it can be detected even at ca. 20 ppb. The MAK value for PH_3 is 0.1 ppm and the TLV value, 0.3 ppm. There are no MAK or TLV limits for any other phosphines, with the exception of phenylphosphine (see Chap. Toxicology).

Phosphine, PH_3, like some other low molecular mass phosphines (e.g., phenylphosphine, methylphosphine, dimethylphosphine, and trimethylphosphine), is very toxic. The LC_{50} and LD_{50} values show that the acute toxicity decreases with increasing molecular mass.

The presence of an electron lone pair gives rise to the three principal properties of the phosphines:

1. Oxidizability
2. Ability to function as a ligand in complexes
3. Nucleophilicity

The physical properties of some primary, secondary, and tertiary phosphines are given in Tables 1-3.

Table 1. Physical properties of primary phosphines

Formula	CAS no.	M_r	Density, g/cm^3	^{31}P NMR, ppm	*bp* at 103 kPa, °C	n_D^{20}	Flash point, °C

2.2. Production

2.2.1. *Primary and Secondary Phosphines*

The radical-induced addition of alkenes to PH_3 produces primary and secondary phosphines with good selectivity, provided that linear α-alkenes are not used. Commercially, 9*H*-9-phosphabicyclononane (American Cyanamid, Hoechst) and diisobutylphosphine [1732-72-5] (American Cyanamid) are produced by this method [11]. Azobisisobutyronitrile (AIBN) is used as the initiator.

Primary phosphines are produced selectively, though only in moderate yield, by the acid-catalyzed reaction of PH_3 with alkenes [12]. In contrast to the radical-catalyzed reaction, this reaction yields Markovnikov products. *tert*-Butylphosphine can be obtained from PH_3 and isobutene in this way. This substance has been proposed as a substitute for high-purity PH_3 for use in the semiconductor industry (American Cyanamid) [13].

2.2.2. *Tertiary Phosphines*

Reaction of PCl_3 with Organometallic Compounds. The Grignard reaction with phosphorus trichloride offers an industrial route to tertiary phosphines (M & T or Atochem, Hokko) [14], [15].

$$PCl_3 + 3\,RMgCl \xrightarrow{-MgCl_2} PR_3$$

R = phenyl, cyclohexyl, butyl, octyl, tolyl

Triphenylphosphine, which is important as a catalyst ligand and as an intermediate in the synthesis of Wittig reagents, is also produced by BASF in a reaction analogous to the Wurtz reaction [16].

$$PCl_3 + 3\,C_6H_5Cl + 6\,Na \longrightarrow P(C_6H_5)_3 + 6\,NaCl$$

Addition of Unsaturated Compounds to PH_3. Trialkylphosphines are obtained by the radical-induced addition of alkenes to PH_3 (American Cyanamid, Hoechst, Nippon Chemical Industries) [17-19].

$$PH_3 + 3\,H_2C{=}CHR \xrightarrow{I} P(CH_2CH_2R)_3$$

R = H, C_nH_{2n+1} (n = 1–18)

I = Initiator (e.g., azobisisobutyronitrile)

Both the Grignard process and the PH_3 route have advantages and disadvantages. For example, trimethylphosphine and triarylphosphines cannot be obtained by the PH_3 process. Only linear α-alkenes react smoothly to give tertiary phosphines, and phosphines with sterically hindered groups are generally not obtainable in this way. On the other hand, the Grignard process has a potential pollution problem due to the byproduct magnesium salts, meaning that extra cost is incurred.

Tris(2-cyanoethyl)phosphine, which is of interest as an intermediate, can be obtained either directly by radical- or base-catalyzed reaction of PH_3 with acrylonitrile [20], or by reacting tris (hydroxymethyl)phosphine [2767-80-8] with acrylonitrile [21]. Tris(hydroxymethyl)phosphine can be obtained by reacting PH_3 with formaldehyde in the presence of metal catalysts (e.g., Cd^{2+}), but is more conveniently produced from the commercially more readily available tetrakis(hydroxymethyl)phosphonium chloride or sulfate (see Chap. Phosphonium Salts) by reaction with aqueous NaOH with loss of one equivalent of formaldehyde.

The industrial production of tertiary phosphines with differing groups on the phosphorus atom is carried out by a number of methods.

Primary or secondary phosphines can be further alkylated with alkenes (sometimes bearing functional groups) under free-radical catalysis.

(1)

One cyanoethyl group of tris(2-cyanoethyl)phosphine can be cleaved under basic conditions if the phosphine compound is first converted to a quaternary compound by treatment with an alkyl halide:

$$P(CH_2CH_2CN)_3 + BrCH_2CH_2CH_2SO_3^-Na^+ \longrightarrow$$

$$(NCCH_2CH_2)_3P^+CH_2CH_2SO_3^- \xrightarrow{CH_3ONa} \qquad (2)$$

$$Na^{+-}O_3SCH_2CH_2P(CH_2CH_2CN)_2$$

This method can be used to produce chiral phosphines with the phosphorus atom as chirality center.

Synthesis from Arylphosphines. Tertiary phosphines with one or two phenyl groups can be obtained either from the corresponding chloroarylphosphines or from triphenylphosphine [22].

2.3. Uses

Primary and secondary phosphines are intermediates, not usually isolated, in the production of tertiary phosphines and their derivatives. Also, phosphinic and dithiophosphinic acids (see Chap. Phosphinic Acids and their Derivatives), obtained by oxidation of secondary phosphines, have been used to a limited extent for solvent extraction and flotation processes (Cyanex 272, Aerofine 3418 A, American Cyanamid). High-purity *tert*-butylphosphine [2501-94-2] (Cypure, American Cyanamid) can partially replace the more toxic PH_3 in the production and doping of semiconductors in the electronics industry [13]

Triphenylphosphine (TPP) has the greatest industrial importance of all the tertiary phosphines as a ligand in homogeneous catalysis (hydroformylation, hydrogenation, and oligomerization), and as a starting material in the preparation of Wittig reagents, especially for the synthesis of vitamin A and in the production of β-carotene [23]. TPP can be sulfonated by a process developed by Rhône-Poulenc and Hoechst. The rhodium complexes of sulfonated TPP used in hydroformylation are water soluble and can therefore easily be separated from the organic phase [24], [25].

The phosphinoethanesulfonate salt, obtainable by Equation (2), is also water-soluble. It is used as an antioxidant and complexing agent for silver in the production of positive transparencies [26].

The tertiary bicyclic phosphines, produced according to Equation (1), enable long chain α-alkenes to be hydroformylated and hydrogenated in high yield to give alcohols for detergents [27].

The ligand formed in Equation (3) is of major industrial importance. It is used as a nickel complex to catalyze the oligomerization of ethylene to form linear α-alkenes in the Shell Higher Olefin Process (SHOP) [28].

Trialkylphosphines are used as starting materials in the production of phosphonium salts (see Chap. Phosphonium Salts) as well as tertiary phosphine oxides and sulfides (see Chap. Phosphine Oxides and Sulfides). They are also used directly as catalysts for the trimerization of diisocyanates [29].

Triethylphosphine functions as a ligand in a gold(I) complex for oral treatment of arthritis (Auranofin, Smith-Kline & French) [30].

[Top of Page]

3. Halophosphines

Jürgen Svara and Norbert Weferling

The halophosphines RPX_2 (phosphonous acid dihalides) and R_2PX (phosphinous acid halides) are important starting materials in the production of numerous organophosphorus compounds.

3.1. Properties

Halophosphines are generally colorless liquids of high density. Due to their high reactivity and water and air sensitivity, they are used only as intermediates in the production of plant protection agents, stabilizers for plastics, and catalysts. Some physical properties of the industrially important compounds are listed in Table 4.

Table 4. Physical properties of halophosphines

Formula	CAS no.	M_r	Density, g/cm^3	*bp* (*p*), °C (Pa)	*mp*, °C	n_D^{20}	Flash point, °C
CH_3PCl_2	[676-83-5]	116.92	1.32	81 (1.03×10^5)	<–64	1.4960	23 [a]
$C_6H_5PCl_2$	[644-97-3]	178.99	1.318	224 (1.03×10^5)	–51	1.5958	102
$Cl_2PC_6H_4C_6H_4PCl_2$	[35346-33-9]	355.96		175 (665)	63		
$(C_6H_5)_2PCl$	[1079-66-9]	220.64	1.19	320 (1.03×10^5)	15	1.634	138 [b]

[a] Pensky – Martens closed cup.
[b] Cleveland open cup.

3.2. Production

From Hydrocarbons and PCl_3. Alkyl- and aryldichlorophosphines are obtained by the free radical reaction of PCl_3 with hydrocarbons in the gas phase at high temperature. Halogen compounds are used as catalysts [31-35]. In the case of aromatic compounds, yellow phosphorus may be added as an additional component [36].

$$CH_4 + PCl_3 \xrightarrow[CCl_4]{550-650\,°C} CH_3PCl_2$$

$$C_6H_6 + PCl_3 \xrightarrow[C_6H_5Cl]{450-600\,°C} C_6H_5PCl_2$$

By the Friedel – Crafts Reaction. The reaction of phosphorus trichloride with aromatic hydrocarbons in the Friedel – Crafts reaction takes place under considerably milder conditions than the gas-phase reaction. However, complexes of halophosphine and $AlCl_3$ are produced, which must be decomposed by adding $POCl_3$, ketones, or esters, forming more stable aluminum chloride complexes [37], [38].

$$C_6H_6 + PCl_3 + AlCl_3 \longrightarrow C_6H_5PCl_2 \cdot AlCl_3 + HCl$$

By the Kinnear – Perren Reaction. Alkyltrichlorophosphonium tetrachloroaluminates can be obtained from phosphorus trichloride, alkyl chlorides, and aluminum trichloride. Alkyldichlorophosphines can be obtained from the phosphonium salts by reduction and complexing the $AlCl_3$.

$$RCl + PCl_3 + AlCl_3 \longrightarrow RPCl_3^+AlCl_4^-$$

$$3\,RPCl_3^+AlCl_4^- \xrightarrow{+2P + 3KCl} 3\,RPCl_2 + 2\,PCl_3 + 3\,KAlCl_4$$

$$3\,RPCl_3^+AlCl_4^- \xrightarrow{+2Al + 5KCl} 3\,RPCl_2 + 5\,KAlCl_4$$

By Disproportionation or Comproportionation. Chlorodiphenylphosphine and PCl_3 are obtained by the disproportionation of dichlorophenylphosphine in the gas phase at elevated

temperature [39]. Similarly, triphenylphosphine or triphenylphosphine oxide can be comproportionated with PCl_3 or dichlorophenylphosphine [40-43].

$$2\,C_6H_5PCl_2 \longrightarrow (C_6H_5)_2PCl + PCl_3$$

$$(C_6H_5)_3P + 2\,PCl_3 \longrightarrow 3\,C_6H_5PCl_2$$

$$(C_6H_5)_3PO + 2\,PCl_3 \longrightarrow 2\,C_6H_5PCl_2 + C_6H_5P(O)Cl_2$$

From Elemental Phosphorus. The reaction of red phosphorus with perfluoroiodoalkanes to give a mixture of perfluoroalkyldiiodophosphine and bis(perfluoroalkyl)iodophosphine is of industrial importance [44].

$$2\,P_{red} + 3\,RI \longrightarrow RPI_2 + R_2PI$$

$$R = C_nF_{2n+1},\ n = 6-12$$

3.3. Uses

Dichloromethylphosphine (Hoechst) [45] is used in the production of methylphosphinic acid [4206-94-4], $CH_3PH(O)OH$, which is used in the production of the total herbicide Gluphosinate. Another application is in the production of a cyclic phosphinocarboxylic anhydride, which is used in the flameproofing sector (see Sections Phosphinic Acids and Phosphinate Esters and Other Phosphinic Acid Derivatives). Dichlorophenylphosphine (Akzo, Ferro Corp.) is converted to phenylphosphinic acid [1779-48-2] by hydrolysis (see Section Phosphinic Acids and Phosphinate Esters), or disproportionated to give chlorodiphenylphosphine. It has largely lost its importance as a precursor for the insecticide EPN (see Section Dialkyl and Diaryl Phosphonates). The bifunctional biphenyl derivative $Cl_2P–C_6H_4–C_6H_4–PCl_2$ [35346-33-9] (Sandoz) is used in the production of the plasticizer Sandostab P-EPQ (see Section Properties and Uses).

Chlorodiphenylphosphine (Akzo) is an important starting material for the production of UV-hardening paint systems (see Section Uses). Mixtures of perfluoroalkyliodophosphines are converted by hydrolysis to perfluoroalkylphosphonic and perfluoroalkylphosphinic acids, which are used for cleaning and degreasing (Fluowet PP, Hoechst).

[Top of Page]

4. Phosphonium Salts [46]

Jürgen Svara and Norbert Weferling

Phosphonium salts are four-coordinate phosphorus compounds of the type $[R_nPH_{4-n}]^+ X^-$, where the phosphorus atom carries a positive charge. In the industrially important phosphonium compounds the group R is alkyl, benzyl, or aryl. The counterion X^- can be organic or inorganic. If both charges are present on the same molecule, the compound is referred to as a phosphabetaine. Phosphonium salts cannot in all cases be easily distinguished from phosphoranes with a five-coordinate phosphorus atom, because they can exist in either form, depending on the solvent and/or the state of aggregation.

4.1. Properties

Phosphonium salts, with few exceptions, are colorless, crystalline solids with good to very good solubility in water. Compounds with short-chain (C_1 – C_4) and long-chain (> C_8) alkyl groups in the same molecule exhibit surfactant properties. Like the corresponding ammonium compounds, they are biocides (see Section Uses), though in general their bactericidal properties are weaker. Their toxicity to fish is lower than that of the corresponding ammonium salts. Many phosphonium salts have an extremely irritant effect on skin and mucous membranes and moderate acute toxicity. They are biologically degraded only very slowly.

Tetraalkylphosphonium salts are oxidized by bases (OH^-, RO^-) with elimination of alkane to give tertiary phosphine oxides only upon prolonged reaction at elevated temperature [47]. Phosphonium salts are thus more stable than the corresponding ammonium compounds under the conditions of phase-transfer catalysis.

Table 5 lists the physical properties of some phosphonium salts.

Table 5. Physical properties of phosphonium salts

Formula	CAS no.	M_r	Density, g/cm^3	^{31}P NMR, ppm	*bp* at 103 kPa, °C	*mp*, °C	Flash point, °C
$[(CH_3)_4P]Cl$	[1941-19-1]	126.57		+24.7	400		> 300
$[(CH_2OH)_4P]Cl$	[124-64-1]	190.56	1.33	+25.2		150	
$[(C_4H_9)_4P]Br$	[3115-68-2]	339.34		+34		95	290
$[(C_4H_9)_3PC_{16}H_{33}]Br$	[14937-45-2]	507.66		+32.6		55	
$[(C_4H_9)_3PCH_3]I$	[1702-42-7]	344.26		+32.0		145	285
$[(C_6H_5)_4P]Br$	[2751-90-8]	419.31		+20.8		295	295 [a]
$[(C_6H_5)_3PCH_2OCH_3]Cl$	[4009-98-7]	342.80				180	

[a] Thermal decomposition.

4.2. Production

From Phosphines by Formation of Quaternary Compounds. Phosphines, R_nPH_{3-n}, like the corresponding nitrogen compounds, form quaternary salts with acids.

$$R_nPH_{3-n} + HX \longrightarrow [R_nPH_{4-n}]\ X^-$$

$$R = \text{alkyl, aryl};\ X = \text{Cl, Br, I}$$

Owing to their nucleophilicity, phosphines react with alkyl and aryl halides to give the corresponding phosphonium salts; the rate of reaction decreases in the order R′I > R′Br > R′Cl.

$$R_3P + R'X \longrightarrow [R_3PR']^+ X^-$$

$$R = \text{alkyl, aryl, H}$$
$$R'X = \text{alkyl or benzyl halide}$$

(Methoxymethyl)triphenylphosphonium chloride is produced by a one-pot variation of this reaction in which triphenylphosphine (TPP) is reacted with acetyl chloride and dimethoxymethane [48]. Chloromethyl methyl ether, formed as an intermediate, alkylates the TPP in a subsequent reaction.

$$Ph_3P + Cl-\overset{O}{\overset{\|}{C}}-CH_3 + CH_3OCH_2OCH_3 \longrightarrow$$
$$CH_3C(O)OCH_3 + [Ph_3PCH_2OCH_3]^+\ Cl^-$$

In the formation of quaternary compounds from aryl bromides or chlorides, the so-called complex salt method is particularly suitable [49], whereby the molar ratio of phosphine to metal salt is 2:1. Nickel halides, and chlorides of cobalt, zinc, and copper(II) can be used.

$$(C_6H_5)_3P + C_6H_5Br \xrightarrow[200°\,C]{NiBr_2} [(C_6H_5)_4P]^+\ Br^-$$

Addition of Phosphines to Carbonyl Compounds. A very effective method of preparing phosphonium salts is the reaction of phosphines with carbonyl compounds in the presence of at least one equivalent of acid. The carbonyl group is inserted into one or more P–H bonds, forming α-hydroxyalkylphosphonium salts.

$$PH_3 + H_2C{=}O + HCl \longrightarrow [P(CH_2OH)_4]^+\ Cl^-$$

HX = mineral acid, carboxylic acid

Addition of 1,3-Dienes to Halophosphines (McCormack Reaction). 1,3-Dienes react with, e.g., dichlorophosphines, to give chlorophospholenium chlorides in a reaction analogous to the Diels – Alder reaction. The formation of the adduct takes place very slowly under normal conditions, but can be accelerated by the use of, e.g., $POCl_3$ as a solvent. Solvolysis of the product yields phospholene oxides (see Chap. Phosphine Oxides and Sulfides).

R = alkyl, aryl; R^1, R^2 = H, alkyl

By Anion Exchange. In cases where the presence of halide ions is undesirable (e.g., where they may cause corrosion), strongly basic ion exchangers are used to replace them by hydroxyl ions, which can themselves be easily exchanged for other anions. In this way, the readily accessible tetraalkylphosphonium halides can be converted to phosphonium acetates, which are used as latent hardeners and accelerators in the production of epoxy resins [50].

4.3. Uses

Few other classes of compounds can match the phosphonium salts for the remarkable variety of their technical applications, though the quantities involved are not always large. These include the use of phosphonium salts derived from triphenylphosphine as Wittig reagent precursors [51], and the use of tetraalkylphosphonium salts as reaction accelerators (phase-transfer catalysts [52] or promoters). The latter are used in several processes, including the production of acetic acid and acetic anhydride by the carbonylation of methanol [53], in the production of stabilizers for polypropylene, and the manufacture of isocyanurate esters [54] and polysiloxanes [55]. Owing to their high thermal stability, they are also suitable for chlorine – fluorine exchange in chloronitro aromatic compounds [56]. The quality of dithiophosphoric acids produced from P_4S_{10} and alcohols is significantly improved by the presence of catalytic amounts of quaternary phosphonium compounds [57].

The biocidal properties of tetraalkylphosphonium salts are exploited in cooling water additives (Belacide, formerly Belclene 350, Ciba-Geigy [58]), in antifouling paints [59], and as additives in drilling oils.

2,4-Dichlorobenzyltributylphosphoniumchloride (Phosfleur (Perifleur Products), Chlorphonium [115-78-6]) is used as a growth regulator for plants of the genus chrysanthemum [60].

Technochemie has specialized in the production of quaternary compounds from triarylphosphines. Albright & Wilson produce tetrakis(hydroxymethyl)phosphonium salts as intermediates for the production of flameproofing agents for cotton textiles (Proban process [61]). Also, all phosphine producers produce phosphonium salts (American Cyanamid, Hoechst, Hokko, M & T, and Nippon).

[Top of Page]

5. Phosphine Oxides and Sulfides

Jürgen Svara and Norbert Weferling

The terms phosphine oxide and phosphine sulfide denote four-coordinate phosphorus compounds with only organic groups or hydrogen atoms present in addition to the P=O or P=S double bond.

5.1. Properties

Primary phosphine oxides, $RH_2P{=}O$, are only stable under normal conditions if the R group stabilizes the molecule by its steric bulk, e.g., 2,4,6-tri(*tert*-butyl)phenylphosphine. Even under mild conditions, disproportionation products (primary phosphine and phosphonous acid) are formed during oxidation of primary phosphines.

Primary phosphine sulfides are also unstable and tend to form cyclic polyphosphines at elevated temperature, with liberation of H_2S.

Secondary phosphine oxides (phosphinous acids) $R_2HP{=}O$ are generally crystalline, colorless, odorless substances that are stable at room temperature. However, they disproportionate at high temperature to form secondary phosphines and phosphinic acids.

$$2\ (CH_3)_2\overset{O}{\overset{\|}{P}}H \xrightarrow{T > 100\,°C} (CH_3)_2PH + (CH_3)_2\overset{O}{\overset{\|}{P}}OH$$

Tertiary phosphine oxides are, with few exceptions, crystalline substances. They are odorless, resistant to hydrolysis, and of low acute toxicity, but are not easily biologically degradable. The physical properties of some phosphine oxides are given in Table 6.

Table 6. Physical properties of phosphine oxides

Formula	CAS no.	M_r	Density g/cm³	^{31}P NMR, ppm	*bp* (*p*), °C (Pa)	*mp*, °C	Flash point, °C

[a] In alkaline medium: 60.2/62.6 ppm.

5.2. Production

Oxidation of Secondary and Tertiary Phosphines. Secondary and tertiary phosphines react smoothly with equimolar amounts of H_2O_2 in aqueous solution or with elemental sulfur in an aprotic organic solvent under mild conditions to form the corresponding secondary and tertiary phosphine oxides or sulfides. These methods are by far the most important for the production of these classes of substances.

$$R_nH_{3-n}P \xrightarrow{+\ H_2O_2/S_8} R_nH_{3-n}P{=}X$$

X = O, S; n = 2, 3

In the reaction of secondary phosphines with H_2O_2, the reaction conditions— especially the reaction temperature—must be chosen so that formation of phosphinic acids is minimized.

Water-soluble tertiary phosphines can be oxidized with water, with liberation of hydrogen.

$$P(CH_2OH)_3 \xrightarrow[-H_2]{H_2O/OH^-} (HOCH_2)_3P{=}O$$

The use of oxygen or air instead of H_2O_2 can be recommended only for the oxidation of secondary phosphines. When tertiary phosphines react with oxygen, the P–C bond is broken, leading to the formation of secondary phosphine oxides, phosphonates, and phosphinates, the tertiary phosphine oxides being obtained only as side products.

By Grignard Reaction. Phosphoryl chloride, phosphinic acid dichlorides, and phosphonic acid chlorides react with Grignard reagents with substitution of the halogen to form tertiary phosphine oxides.

$$POCl_3 \xrightarrow[-3\,MgXCl]{+3\,RMgX} R_3P{=}O$$

$$R^1POCl_2 \xrightarrow[-2\,MgXCl]{+2\,RMgX} R^1R_2P{=}O$$

$$R^1R^2POCl \xrightarrow[-MgXCl]{+RMgX} R^1R^2RP{=}O$$

The industrial production of trioctylphosphine oxide is carried out by this process, among others.

The reaction of the corresponding thio compounds with Grignard reagents often gives diphosphine disulfides as side products.

Secondary phosphites (dialkyl phosphonates) and tertiary phosphites can also be reacted with Grignard reagents to give tertiary phosphine oxides.

Solvolysis of P – Cl Compounds. Monohalophosphines react with water or alcohols to give secondary phosphine oxides, whereas monohalophosphonium salts (dihalophosphoranes) form tertiary phosphine oxides under these conditions.

$$R_2PCl \xrightarrow[-RCl]{+ROH} R_2\overset{O}{\overset{\|}{P}}{-}H$$

(4)

By the Michaelis – Arbusov Reaction. Esters of phosphinous acids react with alkyl halides, generally smoothly and with high yields, to form the metathesis products, with rearrangement of the organophosphorus product to give the tertiary phosphine oxide. Acylphosphine oxides may be obtained by using acyl halides.

R = alkyl, benzyl, benzoyl

By Reaction with Carbonyl Compounds. Carbonyl compounds react readily with secondary phosphines and phosphine oxides with substitution at the P–H bond to give the corresponding tertiary phosphines or phosphine oxides with an α-hydroxyl group.

By Reaction of Phosphinate Esters with Activated Alkenes. Esters of phosphinous acids react smoothly with reactive alkenes in the presence of proton donors (not carboxylic acids) to give tertiary phosphine oxides. Phosphonous acid esters are converted to phosphinic acid esters.

5.3. Uses

Tertiary phosphine oxides and sulfides are used almost entirely as solvent extraction media [62]. Trioctylphosphine oxide (TOPO) is of particular importance (Cyanex 921, American Cyanamid; Hostarex PX 324, Hoechst; Hokko), being used for the extraction of metal ions [63-65] or carboxylic acids, alcohols, and phenol from aqueous solutions [66], [67]. Products such as Cyanex 923 (American Cyanamid, a mixture of tertiary phosphine oxides containing hexyl and octyl groups), and Hostarex PX 320 (Hoechst, *sec*-butyldioctylphosphine oxide) were also developed for this application [68], [69]. Cyanex 471 X (American Cyanamid, triisobutylphosphine sulfide) is used for the extraction of noble metals (silver, platinum, and palladium) and mercury from strongly acidic solutions [70]. The use of tertiary phosphine oxides as catalysts is still restricted to a few reactions, though these are of economic importance. Phospholene oxides [71], which can be obtained, for example, by Equation (4), catalyze the formation of carbodiimides from isocyanates [71], and of polyamides and polyimides [72]. A further application is the production of lactones from acid chlorides [73]. Tertiary phosphine oxides can also be used for stabilizing peroxycarboxylic acids in detergents [74].

Bifunctional phosphine oxides, such as *sec*-butyl-bis(3-hydroxypropyl)phosphine oxide or 1-hydroxy-1-dimethylphosphinoacetic acid are reactive flameproofing agents [75] and herbicides [76], respectively.

Mono- and bis-acylphosphine oxides are used as initiators for the hardening of photopolymerizable materials by UV radiation [77]. They are especially suitable for hardening white paints [78] and dental materials [79].

[Top of Page]

6. Phosphonous Acid Derivatives

Jürgen Svara and Norbert Weferling

Organic derivatives of phosphonous acid are formally derived from the hypothetical phosphonous acid $H–P(OH)_2$. Structures containing three-coordinate phosphorus are only stable if both hydroxyl groups are blocked, for example, by esterification (**1**) or amide formation (**2**). Monoesters (**3**), however, contain four-coordinate phosphorus and are regarded as derivatives of phosphinic acid $H_2P(=O)OH$. Phosphonous acid dihalides (dichlorophosphines) $R–PX_2$ are treated in Chapter Halophosphines.

1 **2** **3**

6.1. Production

Diesters of phosphonous acid are formed by reacting dihalophosphines with alcohols in the presence of bases, or by reacting phosphorous acid diester chlorides with Grignard reagents.

Phosphonous acid diamides can be obtained from dihalophosphines and amines, or from phosphorous acid diamide halides and Grignard reagents.

6.2. Properties and Uses

Phosphonous acid derivatives are generally readily oxidized to phosphonic acid derivatives. Although the phosphorus – carbon bond is very stable, hydrolytic cleavage of the bond between the phosphorus atom and the hetero atoms takes place even under mild conditions. The tetraester of a diphosphonous acid **4** is used under the names Sandostab P-EPQ (Sandoz) and Irgafos P-EPQ (Ciba-Geigy) for the thermal stabilization of plastics [80], [81].

4 [*38613-77-3*]

[Top of Page]

7. Phosphinic Acids and their Derivatives

Jürgen Svara and Norbert Weferling

Organophosphinic acids are the organic derivatives of phosphinic acid (hypophosphorous acid), $H_2P(=O)OH$, in which one or both of the hydrogen atoms on the phosphorus atom are replaced by organic groups. The free acids are of industrial importance, as are the esters, halides, and thio derivatives.

7.1. Properties

The phosphorus – carbon bonds in diorganophosphinic acids (with the exception of α-hydroxyalkyl, alkoxy, or trihalomethyl compounds) are very stable to hydrolysis under both acid and alkaline conditions. Long-chain substituted phosphinic acids and their dithio analogues form stable complexes with divalent cations, and are used in flotation and metal extraction. A number of phosphinic acid derivatives are intermediates in the production of flameproofing and crop protection agents.

7.2. Production

By Hydrolysis of Halophosphines. Organophosphinic acids are obtained by the hydrolysis of dihalophosphines under nonoxidizing conditions.

By Oxidation. Secondary phosphines, phosphine oxides, or halophosphines are oxidized to phosphinic acid derivatives by oxygen, sulfur, halogens, or other oxidizing agents. The most important industrial processes are the oxidation and sulfurization of secondary phosphines [82].

By the Michaelis – Arbusov Reaction (see Section By the Michaelis – Arbusov Reaction.). Alkyl diorganophosphinates are obtained by reacting dialkyl esters of phosphonous acid with alkyl halides.

By Addition to Double Bonds. Organophosphinates RHP(=O)OH and their esters can add to compounds containing C=C, C=O, or C=N double bonds in the presence of catalysts [83-85]. Phosphinic acid (hypophosphorous acid) H_3PO_2 [6303-21-5] undergoes double addition to yield symmetrically substituted diorganophosphinates.

Dihalophosphines react with α, β-unsaturated carboxylic acids to form the dichlorides of carboxyalkylalkylphosphinic acids, which can be converted to cyclic anhydrides [86-88].

From Tertiary Phosphine Oxides. Treatment of tertiary phosphine oxides with alkali-metal hydroxides at elevated temperature usually causes the most electronegative substituent to be cleaved as an alkane or arene, forming alkali-metal salts of diorganophosphinic acids [89].

$$R_2R'P{=}O + NaOH \xrightarrow{200-300°C} R_2P(=O)ONa + R'H$$

7.3. Phosphinic Acids and Phosphinate Esters

Methylphosphinic acid [4206-94-4], $CH_3PH(=O)OH$, is used in the production of the total herbicide Gluphosinate (Phosphinothricin) [53369-07-6] (Basta, Hoechst), which is used in the form of its ammonium salt [77182-82-2] [90], [91]. The synthesis takes place via the intermediate compound isobutyl methylphosphinate [25296-66-6] or the isoamyl ester [87025-51-2].

[53369-07-6]

Phenylphosphinic acid [1779-48-2], $C_6H_5PH(=O)OH$, and its sodium salt [4297-95-4] (Akzo, Ferro Corp.) are used to improve the stability of polyamides towards light and heat, and as antioxidants and promoters for emulsion polymerization.

Bis(hydroxymethyl)phosphinic acid [2074-67-1] is an intermediate in the synthesis of crop protection agents [85]. The calcium or magnesium salts (Chemische Fabrik Budenheim) are used as binders in basic fire-resistant materials [92]. The longer chain compounds bis(2,4,4-trimethylpentyl)phosphinic acid [83411-71-6] (Cyanex 272, American Cyanamid) and bis(2-ethylhexyl)phosphinic acid [298-07-7] (P-229, People's Republic of China) are used as extractants in the hydrometallurgical separation of cobalt and nickel [93].

7.4. Thiophosphinates

Thio derivatives of phosphinic acids are mainly used in ore and metal processing. The sodium salt of bis(2-methylpropyl)dithiophosphinic acid [13360-80-0] (Aerophine 3418 A) is supplied by American Cyanamid as a flotation agent for sulfidic ores. Bis(2,4,4-trimethylpentyl)dithiophosphinic acid [107667-02-7] (Cyanex 301, American Cyanamid) has better solubility in organic solvents and is suitable for extracting zinc and other heavy metals [93].

7.5. Other Phosphinic Acid Derivatives

The cyclic phosphinic anhydride 2-methyl- 2,5-dioxo-1,2-oxaphospholane (or 2-methyl-1,2-oxaphospholane-5-one 2-oxide) [15171-48-9] is of major importance in the production of washable fireproofed textiles, and are incorporated into polyester fibers by copolymerization (Trevira CS, Hoechst).

[Top of Page]

8. Phosphites and Hydrogenphosphonates

Jürgen Svara and Norbert Weferling

Phosphites are organic esters of the hypothetical phosphorous acid $P(OH)_3$ in which all three OH groups are esterified. In the mono- and diesters, the phosphorus is four-coordinate. They are therefore formal derivatives of phosphonic acid $(HO)_2P(O)H$ (phosphonates). However, both the properties and the uses of the phosphites and the hydrogenphosphonates are so closely related that treatment together is appropriate.

Hydrogenphosphonates and phosphites are mainly used as raw materials for insecticides (⟶ Insect Control) as flameproofing agents, and as stabilizers and antioxidants for plastics (⟶ Antioxidants – Phosphorus Compounds).

8.1. Properties

Hydrogenphosphonates and phosphites are colorless liquids or solids. Owing to their structure, phosphites and phosphonic acid diesters are neutral compounds, while the monoesters have strongly acidic properties. All these compounds are readily hydrolyzable and are susceptible to oxidation. These properties make them suitable as stabilizers for plastics, in which they act by reducing peroxides and by capturing reactive radicals.

8.2. Production

Phosphites and hydrogenphosphonates are usually produced by reacting alcohols or phenols with phosphorus trichloride.

$$PCl_3 + 3\,ArOH \longrightarrow (ArO)_3P + 3\,HCl$$

Whereas reaction of PCl_3 with 3 mol phenol yields the desired triaryl phosphite with liberation of hydrogen chloride, alcohols react to form dialkyl phosphonates and alkyl chloride.

To produce the trialkyl esters, it is necessary to add an equimolar amount of a substance that will neutralize acid. As a rule, ammonia or a volatile amine is used in an inert solvent in which the ammonium chloride formed is sparingly soluble and can be removed by filtration.

The esterification of H_3PO_3 with alcohols to give dialkyl phosphonates is of less importance [96]. The addition of ethylene oxide to PCl_3 in the presence of catalytic quantities of chloroethanol, iron chloride, or aluminum chloride produces tris(2-chloroethyl) phosphite.

Triphenyl phosphite can be reacted with alcohols to give a mixture of phenyl dialkyl and alkyl diphenyl phosphites.

$$(ArO)_3P + ROH \longrightarrow (ArO)_2POR + ArOH$$

$$(ArO)_3P + 2\,ROH \longrightarrow ArOP(OR)_2 + 2\,ArOH$$

8.3. Trialkyl Phosphites

Some physical properties of the most important trialkyl phosphites are listed in Table 7.

Table 7. Physical properties of trialkyl phosphites $(RO)_3P$

The short-chain compounds are mainly used as starting materials in the production of dialkyl esters of phosphonic acid (Michaelis – Arbusov reaction, see Section Production).

In a further important application, they are converted into insecticidal vinyl esters of phosphoric acid [97]. Manufacturers of trialkyl phosphites include Albright & Wilson, Bayer, and Ciba-Geigy.

The long-chain compounds are mainly used as antioxidants for plastics [98], [99]. Spirocyclic compounds are also used in this application. These are obtained from pentaerythritol [115-77-5] and long- chain alcohols. Manufacturers: Albright & Wilson, Akzo, and Borg-Warner.

The main areas of application are in the production of phosphonic acid derivatives, insecticides, and plastics additives. Technical-grade diphenyl phosphite is produced by hydrolysis of triphenyl phosphite with water, and usually contains considerable quantities of free phenol. A low-phenol product is obtained by reacting triphenyl phosphite with phosphonic acid.

8.6. Alkyl Phosphonates

Alkyl phosphonates are not of great industrial importance, an exception being monoethyl phosphonate, which is marketed as a fungicide in the form of the aluminum salt $Al[C_2H_5OPH(=O)O]_3$ [39148-24-8] (Fosetyl-Aluminum, Aliette, Rhône-Poulenc) [100], [101].

[Top of Page]

9. Phosphonic Acids and their Derivatives

Jürgen Svara and Norbert Weferling

Of all the various types of organophosphorus compounds, phosphonic acids and their derivatives are outstanding due to their structural variety and great economic importance.

Phosphonic acid derivatives are used as crop protection agents (⟶ Weed Control) in water treatment, in metal processing, and as flameproofing agents.

9.1. Properties

The dibasic phosphonic acids are mostly weaker acids than phosphoric acid. The P–C bond in phosphonic acid derivatives is generally very stable towards oxidation or hydrolysis, so that many reactions can be carried out on the organic part of the molecule. Phosphonic acids are often only slowly biodegradable, but are usually rapidly destroyed by a series of photolytic and biological degradation steps. However, compounds with electronegative substituents on the α-carbon atom are considerably less stable.

Several di- and polyphosphonic acids exhibit complexing (sequestering) properties towards polyvalent cations, and, when added in substoichiometric amounts, prevent the precipitation of low-solubility salts such as alkaline earth sulfates or carbonates (threshold effect).

Esters of phosphonic acid are usually more stable to hydrolysis than the corresponding phosphates, but are converted into free phosphonic acids on heating under acid conditions.

9.2. Production

By Oxidation. The oxidation of low-valency organophosphorus compounds is important mainly in the case of the thiophosphonic acid chlorides. This method is used in the production of methylphosphonic acid dichloride [676-97-1] by reaction of methyldichlorophosphine with sulfuryl chloride or chlorosulfuric acid [102]. Elemental sulfur reacts with $MePCl_2$ in the presence of catalytic quantities of tetraalkylphosphonium salts [103] to form methylthiophosphonic acid dichloride [676-98-2].

From Organometallic Compounds. Ethylthiophosphonic acid dichloride [993-43-1], $C_2H_5P(=S)Cl_2$, is prepared by the reaction of thiophosphoryl chloride with $(C_2H_5)_3Al_2Cl_3$ or $(C_2H_5)_3Al$ (Ethyl process) [104], [105].

By the Michaelis – Arbusov Reaction. One of the most important reactions in organophosphorus chemistry is the Michaelis – Arbusov reaction, in which compounds containing three-coordinate phosphorus and at least one alkoxy or alkylthio group react with an alkylating agent R′X, forming a phosphorus – carbon bond in compounds with coordination number 4 [106], [107].

The intermediate phosphonium compounds can only be isolated in exceptional cases. They react further by loss of alkyl halide RX. If R=R′, isomerization occurs with only catalytic quantities of alkylating agent. The method offers a great variety of possibilities, owing to the large range of possible groups R and R′.

Industrially important starting materials for the Michaelis – Arbusov reaction are trialkyl phosphites $P(OR)_3$, which are converted to dialkyl esters of alkanephosphonic acid and to esters of phosphonocarboxylic acids, from which the free phosphonic acids are obtainable by hydrolysis.

$$(C_2H_5O)_3P + ClCH_2COOC_2H_5 \longrightarrow (C_2H_5O)_2\overset{O}{\overset{\|}{P}}CH_2COOC_2H_5 + C_2H_5Cl$$

If α-halocarbonyl compounds are used as the alkylating agents, vinyl esters of phosphoric acid are obtained (Perkow reaction, see Chap. Esters of Phosphoric Acid).

By Addition to C=C Double Bonds. Dialkyl phosphonates undergo base-catalyzed addition to activated C=C double bonds. The reaction is mainly used for the production of phosphonocarboxylate esters, and can be carried out as a continuous process [108]. In the presence of a radical initiator, nonactivated alkenes can also be used.

By the Quasi-Mannich Reaction. Phosphonic (phosphorous) acid H_3PO_3 or its dialkyl esters react with mixtures of formaldehyde with ammonia or amines under acidic conditions to give oligo(methylenephosphonates). When oligo-(ethylene)amines are used, the industrially important poly(methylenephosphonic acids) are formed.

$$NH_3 + CH_2O + H_3PO_3 \xrightarrow{H^+} N(CH_2PO_3H_2)_3$$

By Acylation of Phosphonic Acid. The reaction of phosphonic acid with acetyl chloride or acetic anhydride yields 1-hydroxyethane-1,1-diphosphonic acid [2809-21-4] after hydrolysis.

Alternative starting materials are PCl_3 and acetic acid in the presence of water [109].

The reaction can also be carried out with other carboxylic acid derivatives [110-113]. For example, with acetonitrile, 1-aminoethane-1,1-diphosphonic acid [15049-85-1] is obtained.

9.3. Phosphonic Acids and Phosphonocarboxylic Acids

Methylphosphonic acid [993-13-5] (Ciba-Geigy) is used in the production of lubricant additives and for treating textiles [114], [115]. Octylphosphonic acid [4724-48-5] (Hoechst) is used as a selective collector for the flotation of cassiterite (tin ore). Vinylphosphonic acid [1746-03-8] (Hoechst) [116], [117] or its polymers are used for the surface treatment of aluminum in the manufacture of printing plates [118]. Phenylphosphonic acid [1571-33-1] (Akzo) is used as a catalyst in the production of resins and for manufacturing stabilizers for plastics.

Salts of phosphonoformic acid and phosphonoacetic acid (**5**) have virostatic properties. Trisodium phosphonoformate (**6**) (Foscarnet) is used in the treatment of herpes (Triapten, formerly VEB Germed) or cytomegalic infections in humans (Foscavir, Astra).

5 [*4408-78-0*] **6** [*34156-56-4*]

2-Phosphonobutane-1,2,4-tricarboxylic acid (**7**) [37971-36-1] (NH_4 salt [70233-62-4], Bayhibit AM, Bayer) is used in industrial water treatment on account of its complexing properties.

7 [*37971-36-1*]

Geminal diphosphonic acids are used in the same application, and in washing and cleaning agents, peroxide stabilizers, and many other areas. Compounds of this type include 1-hydroxyethane-1,1-diphosphonic acid [2809-21-4] (Briquest ADPA, Albright & Wilson; Sequion 10 H 60, Bozetto; Turpinal SL, Henkel; Jaypol 210, M & J Polymers; Dequest 2010/2016, Monsanto; Mykon P60, Warwick) and 1-aminoethane-1,1-diphosphonic acid [15049-85-1] (BK Ladenburg), as well as the large group of poly(methylenephosphonic acids) produced from ammonia or ethylene amines. Some important products are nitrilotris(methylenephosphonic acid) [6419-19-8], ethylenediaminetetrakis(methylenephosphonic acid) [1429-50-1] and diethylenetriaminepentakis(methylenephosphonic acid) [15827-60-8]. Producers (trade names) are: Albright & Wilson (Briquest), Bozetto (Sequion), M & J Polymers (Jaypol), Monsanto (Dequest).

The total herbicide *N*-carboxymethylaminomethanephosphonic acid (*N*-phosphonomethylglycine) [1071-83-6], Glyphosate (Roundup, Monsanto) is outstanding for its effectiveness and ease of biodegradability. It is used in the form of its isopropylammonium salt [38641-94-0]. The sodium salt of 2-chloroethylphosphonic acid [16672-87-0] Ethepon (Ethrel, Union Carbide) causes accelerated ripening of fruit by releasing the ripening hormone ethylene in the plant.

[*1071-83-6*] [*16672-87-0*]

9.4. Esters of Phosphonic Acid

Monoesters of phosphonic acid are used in industry only to a limited extent. Salts of short-chain alkyl alkylphosphonates have a flameproofing effect [119], [120]. The 2-ethylhexyl ester of 2-ethylhexylphosphonic acid (**8**) (PC-88A, Daihachi; Ionquest 801, Albright & Wilson) is used as an extractant for lanthanides and for the separation of cobalt and nickel [121].

8 [*14802-03-0*]

9 [*867-13-0*] **10** [*20120-33-6*]

Dialkyl alkylphosphonates are used as flameproofing agents, metal extractants, plasticizers, lubricant additives, and chemical intermediates. The more important compounds are listed in Table 10 with their physical properties. Producers of the methyl compound DMMP include Akzo, Albright & Wilson, Bayer, Ciba-Geigy, and Courtaulds. Other compounds are produced by Albright & Wilson and Daihachi.

Table 10. Physical properties of dialkyl alkylphosphonates RP(=O)(OR)$_2$

Diethyl ethoxycarbonylmethylphosphonate (**9**) (triethyl phosphonoacetate; PEE, Hoechst) is used as a stabilizer for polyesters [122]. Esters of phenylmethylphosphonic acid with bulky substituents (Irganox 1222 [976-56-7] and 1093 [3135-18-0], Ciba-Geigy) are sold as antioxidants and high-temperature stabilizers for polyamides, polyesters, polyolefins and polyurethane foams.

R = C_2H_5; [*976-56-7*]
R = $C_{18}H_{37}$; [*3135-18-0*]

A wide range of other phosphonate esters, often containing chlorine, are used as flameproofing agents. Producers (trade names) are: Akzo (Fyrol, Victastab), Albright & Wilson (Amgard, Antiblaze), Sandoz (Sandoflam 5087). Dimethyl 3-hydroxymethylamino-3-oxopropanephosphonate (**10**) is of particular importance in the production of washable flameproofed cellulose textiles (Pyrovatex CP, Ciba-Geigy) [123-125].

9.5. Other Derivatives of Phosphonic Acid

Halides of phosphonic and thiophosphonic acids are mainly used in the synthesis of crop protection agents. Ehylthiophosphonic acid dichloride is used in the production of the insecticide Fonofos [944-22-9] (Dyfonate, ICI) and Trichloronat [327-98-0] (Agrisil, Phytosol, Bayer), and benzenethiophosphonic acid dichloride [126] in the production of *O*-2,4-dichlorophenyl *O*-ethyl phenylphosphonothioate (S-Seven) [3792-59-4] and EPN [2104-64-5] (both Nissan Chemical Industries).

The acid halides are produced by Akzo, Ethyl, Ferro, and Nissan Chemical Industries. Physical properties are listed in Table 11.

Table 11. Physical properties of phosphonic and thiophosphonic acid halides

10. Esters of Phosphoric Acid

Jürgen Svara and Norbert Weferling

The esters of phosphoric acid constitute an important group of organophosphorus compounds with a broad application as cleaning agents and emulsifiers, textile improvers, plasticizers and flameproofing agents for plastics, anticorrosion agents, and extractants in hydrometallurgy. Phosphoric acid ester chlorides are starting materials in the production of crop protection agents. Many vinyl esters of phosphoric acid have insecticidal properties (⟶ Insect Control – Vinyl Phosphates).

10.1. Properties

Phosphate esters are colorless liquids or crystalline or waxy solids, depending on the substituents. The triesters are neutral compounds, while the mono- and diesters are strongly acidic. The esters of phosphoric acid hydrolyze in the presence of water. The rate of hydrolysis varies widely and depends on the degree of esterification and the nature of the substituents.

10.2. Production

The important raw materials for the production of esters of phosphoric acid are phosphoryl chloride, phosphorus pentoxide, polyphosphoric acid, and trialkyl phosphites.

Phosphorus oxychloride reacts with phenols to form triaryl phosphates. With aliphatic alcohols, the hydrogen chloride formed must be removed by vacuum or by purging with an inert gas. Alternatively, bases may be added.

$$POCl_3 + 3\,ROH \longrightarrow (RO)_3PO + 3\,HCl$$

If a substoichiometric amount of alcohol is used, ester chlorides of phosphoric acid are formed. However, diester chlorides of phosphoric acid are better obtained by reacting dialkyl phosphonates with chlorine or sulfuryl chloride.

The addition of ethylene oxide or propylene oxide to $POCl_3$ at 40 – 100 °C affords tris(2-chloroethyl) or tris(2-chloropropyl) phosphate. To ensure complete reaction, catalysts must be added ($AlCl_3$, $TiCl_4$, PCl_3).

A mixture of mono- and diesters is formed when alcohols or phenols are reacted with phosphorus pentoxide, while the reaction with polyphosphoric acid yields monoesters of phosphoric acid and free phosphoric acid.

$$P_4O_{10} + 6\,ROH \longrightarrow 2(RO)_2PO(OH) + 2\,ROPO(OH)_2$$

$$H_6P_4O_{13} + 3\,ROH \longrightarrow 3\,ROPO(OH)_2 + H_3PO_4$$

An important method for the production of insecticidal vinyl phosphates is the reaction between trialkylphosphites and α-halocarbonyl compounds (Perkow reaction) [127].

10.3. Trialkyl Phosphates

Table 12 gives a survey of the important trialkyl phosphates.

Table 12. Physical properties of trialkyl phosphates $(RO)_3PO$

[a] Cleveland open cup. [b] Decomposes.

Triethyl phosphate is used as a catalyst in the production of acetic anhydride by the ketene process, as a desensitizing agent for peroxides, and as a solvent and plasticizer for cellulose acetate. Tributyl phosphate is used for solvent extraction in hydrometallurgy. Tris(2-ethylhexyl) phosphate is used as a solvent in the production of hydrogen peroxide and is also used as a plasticizer with flameproofing properties. The important producers of trialkyl phosphates are Akzo, Albright & Wilson, Bayer, Daihachi Chemical Industry, and FMC.

Tris(chloroalkyl) phosphates are used as fire retardants for polyurethane foams, polyesters, and other plastics [128]. In addition to the compounds listed in Table 12, a large number of other halogen-containing, sometimes oligomeric trialkyl phosphates with mixed ester groups are marketed as flameproofing agents. Producers (trade name) are: Albright & Wilson (Amgard), Akzo (Fyrol), Bayer (Disflamoll), Courtaulds, Great Lakes Chemical Corp. (Firemaster), Hoechst (Genomoll), Olin (Thermolin), and Sandoz (Sandoflam).

10.4. Triaryl and Alkyl Aryl Phosphates

Some important aromatic triesters of phosphoric acid are listed in Table 13.

Table 13. Physical properties of triaryl phosphates $(R^1O)_3PO$ and alkyl aryl phosphates $(R^1O)(R^2O)_2PO$

R^1	R^2	CAS no.	M_r	Density, g/cm^3	*bp* (*p*), °C (Pa)	n_D^{20}	Flash point, °C

These compounds are mainly used as flameproofing and plasticizing agents for plastics, as lubricants, and as low-flammability hydraulic fluids. Mixtures of isomers are mainly used, based on technical-grade alkyl phenols.

Some producers (trade names) are: Akzo (Phosflex), Albright & Wilson (Pliabrac), Bayer (Disflamoll), Ciba-Geigy (Reofos), FMC (Kronitex), Monsanto (Santicizer).

10.5. Mono- and Dialkyl Phosphates

Only a small number of pure compounds in this class are of industrial importance. Bis(2-ethylhexyl) phosphate [298-07-7] DEHPA, is used in hydrometallurgy as an extraction solvent for a large number of metals. It is produced by chlorinating bis(2-ethylhexyl) phosphonate [3658-48-8] to give the phosphate diester chloride, followed by hydrolysis [129], or by saponification of tris(2-ethylhexyl) phosphate [78-42-2]. It is produced by Albright & Wilson, Bayer, Daihachi, and Hoechst. Products with a high monoester content, obtained from ethoxylated alcohols, are used as defoamers in washing powders (Sokalan S, BASF).

Esters of thiophosphoric acid are used in plant protection (⟶ Insect Control; ⟶ Fungicides, Agricultural) and as flotation agents in ore preparation, lubricant additives, for solvent extraction of metals, and in rubber production.

Mixtures of mono- and diesters of phosphoric acid are of major industrial importance. Their properties can be varied over a wide range by choice of the alcohol or phenol. Ethoxylated alcohols are most commonly used. The wide range of applications includes emulsifiers in plant protection, cleaning agents, cosmetics, and in the paper and textile industries. Mixtures of mono- and diesters are also used as acid hardeners for resins. Manufacturers (trade names) include Akzo (Dapral, Victawet), Albright & Wilson (Albrite, Briphos, Duraphos), GAF (Gafac), Henkel (Disponil), Hoechst (Hostaphat, Leomin, Knapsack phosphate esters), Hüls (Marlophor), and Rhône-Poulenc (Celanol, Soprophor).

Mixtures of monoesters of phosphoric acid with free phosphoric acid are also marketed. These are mainly used as components of detergents (Hoechst).

[Top of Page]

11. Esters of Thiophosphoric Acid

Jürgen Svara and Norbert Weferling

The esters of thiophosphoric acid are formally derived by the replacement by sulfur of one or more of the oxygen atoms bonded to phosphorus in esters of phosphoric acid. Thiophosphoric acids form mono-, di-, and triesters, the location of the organic substituent being indicated as *O*- or *S*-. Of the large range of possible compounds, the derivatives of mono- and dithiophosphoric acid have attained the greatest industrial importance.

11.1. Properties

Thiophosphate esters generally have an unpleasant smell and in the pure state are colorless liquids or solids. The triesters are neutral, while the mono- and diesters are strongly acidic. Technical-grade *O*,*O*-dialkyl dithiophosphates usually have a greenish or yellowish color due to traces of heavy metals. The short-chain compounds in particular cannot be stored indefinitely, and are usually immediately converted into other products. The thermal and hydrolytic stability increases with increasing alkyl chain length and degree of esterification and upon salt formation, so that diaryl dithiophosphates are more easily hydrolyzed than alkyl esters of comparable chain length [130].

Many esters of thiophosphoric acid have high biological activity as acetylcholine esterase inhibitors and are therefore useful insecticides. However, the toxicity to warm-blooded animals is very high. The compounds are decomposed to less toxic products on contact with the soil, as they are readily hydrolyzed.

11.2. Production

Important raw materials for the production of esters of thiophosphoric acid include phosphorus pentasulfide, thiophosphoryl chloride, and dialkyl hydrogenphosphonates.

Phosphorus pentasulfide reacts with alcohols or phenols with loss of H_2S to form the industrially important *O*,*O*-diesters of dithiophosphoric acid. Addition of catalytic nitrogen, phosphorus, or sulfur compounds (e.g., phosphonium halides) improves the yield of the reaction and the product quality [131-133].

In practice, a suspension of phosphorus pentasulfide in the end product is reacted with excess alcohol at 60 – 80 °C. Due to their lower reactivity, phenols must be reacted at 80 – 120 °C. The hydrogen sulfide produced is burnt, and the sulfur dioxide formed is removed by scrubbing with alkali.

O,*O*-Dialkyl esters of dithiophosphoric acid are converted to *O*,*O*-diester chlorides of thiophosphoric acid by reaction with chlorine. Depending on the conditions, the byproducts are hydrogen chloride and disulfur dichloride [10025-67-9] or sulfur.

Another route to this class of compounds is the reaction of thiophosphoryl chloride with alcohols in the presence of acid acceptors.

Salts of thiophosphoric acid are produced by reacting dialkyl hydrogen phosphonates with sulfur in the presence of a base (e.g., ammonia). The *O*,*O*-diesters of thiophosphoric acid are liberated from these compounds by reaction with phosphoric acid.

11.3. Monothiophosphates

O,*O*-Diesters of thiophosphoric acid are used as extraction solvents for heavy metals, especially zinc, or as lubricant additives. The *O*,*O*-diester of thiophosphoric anhydride (**11**) (Sandoflam 5060, Sandoz) is used as a halogen-free flameproofing agent for low-density polyethylene films.

11 [*4090-51-1*]

The alkylation of *O*,*O*-dialkyl thiophosphates usually gives mixtures of *O*,*O*,*O*- and *O*,*O*,*S*-triesters of thiophosphoric acid, some of which are used in crop protection.

The *O,O*-diester chlorides of thiophosphoric acid are very important in the synthesis of crop protection agents, and are usually reacted with phenols or their salts to give insecticidal or fungicidal *O,O,O*-triesters of thiophosphoric acid (Parathion [56-38-2], Methylparathion [298-00-0] ⟶ Insect Control; Pyrazophos [13457-18-6] ⟶ Fungicides, Agricultural). The most important intermediates are *O,O*-dimethoxylthiophosphoryl chloride [2524-03-0], $(CH_3O)_2PSCl$, (M_r 160.56, *bp* 70 – 72 °C (270 Pa), ϱ 1.305 g/cm^3, n_D^{20} 1.4807, flash point 101 °C, colorless liquid (Cheminova), and *O,O*-diethoxylthiophosphoryl chloride [2524-04-1], $(C_2H_5O)_2PSCl$, (M_r188.61, *bp* 71 – 72 °C (93 Pa), ϱ 1.200 g/cm^3, n_D^{20} 1.4688, flash point 106 °C, colorless liquid (Albright & Wilson, Cheminova).

11.4. Dithiophosphates

The *O,O*-diesters of dithiophosphoric acid and aqueous solutions of sodium or ammonium dithiophosphates are used as flotation agents for sulfidic copper and cadmium ores. A new application of increasing importance is the extraction of cadmium from wet phosphoric acid by formation of insoluble complex salts [134-136]. The *O,O*-dialkyl dithiophosphates of short to medium chain length (C_2 – C_8) are particularly effective in this application. The amount added is ca. 0.3 %, depending on the origin of the crude phosphoric acid and the temperature. Preliminary reduction of the acid with iron improves the efficiency of separation of the cadmium [137].

The zinc salts of long-chain esters are used as lubricant additives to improve high-pressure lubrication properties, and useful life of the lubricant [138] (⟶ Lubricants and Lubrication). They are produced by reacting zinc oxide with the alcohol-containing *O,O*-diesters of dithiophosphoric acid. The crude product is recovered by pressure filtration, and the water liberated in the reaction and the excess alcohol are then removed by vacuum distillation.

These products protect the metal surface by forming a sulfide and thiophosphate layer, by removing oxidation products from the lubricant, and by corrosion inhibition.

Water-insoluble *O,O*-dialkyl esters of dithiophosphoric acid can be used as extractants for the hydrometallurgical removal of heavy metals such as zinc from dilute acidic solutions, and are therefore of interest for the treatment of wastewater and polluted groundwater.

An important reaction of *O,O*-dialkyl dithiophosphates is the addition of an activated C= C double bond to form *O,O,S*-triesters of dithiophosphoric acid. Thus, *O,O*-dimethyl dithiophosphate [756-80-9] and diethyl maleate react to produce the insecticide Malathion [121-75-5].

The addition to C = O double bonds is the key reaction in the synthesis of the insecticide Terbufos [13071-79-9] from *O,O*-diethyldithiophosphoric acid [298-06-6], formaldehyde, and 2-methyl-2-propanethiol [75-66-1].

O,O-Dialkyl dithiophosphates are alkylated at the sulfur atom by alkyl halides. This reaction is used to produce numerous insecticidal *O,O,S*-triesters of dithiophosphoric acid.

Alkyl Dithiophosphates. The physical properties of the most important *O,O*-dialkyl dithiophosphates are given in Table 14.

Table 14. Physical properties of *O*, *O*-dialkyl dithiophosphates $(RO)_2P(S)SH$

R	CAS no.	M_r	Density, g/cm^3	*bp* (*p*), °C (Pa)	n_D^{20}	Flash point, °C

[a] Cleveland open cup. [b] Pensky–Martens closed cup.

Most long-chain compounds are produced from mixtures of alcohols. Manufacturers include Albright & Wilson, American Cyanamid, Cheminova, and Hoechst. Aqueous solutions of the salts are marketed as flotation agents by American Cyanamid (Aerofloat) and Hoechst (Hostaflot). Lubricant additives based on the zinc salt are supplied by Chevron and Lubrizol.

Aryl Dithiophosphates. An important compound of this type is dicresyl dithiophosphoric acid [27157-94-4] $(CH_3C_6H_4O)_2P(S)SH$ (M_r 279.41, brown liquid), used as a flotation agent for sulfidic ores. The commercial product is not usually a pure substance, being the reaction product of a mixture of phenol, cresols, and xylenols with phosphorus pentasulfide. Both the free acid and an aqueous solution of the ammonium salt are commercial products (Aerofloat 25, 31, 242, American Cyanamid; Phosokresol B, C, E, Hoechst).

[Top of Page]

12. Economic Aspects

Jürgen Svara and Norbert Weferling

Measured by the tonnage of inorganic phosphorus-containing base materials, e.g., PCl_3 and $POCl_3$, used in their production, the organophosphorus products discussed here are of minor importance. Based on value, the comparison is more favorable, as they are all value-added products, the value of some specialized products being very high. However, for reasons of industrial secrecy, there is very little information available from the manufacturers concerning production quantities and values, so that some of the figures given here are only estimates.

Of the phosphines, triphenylphosphine is the largest product from the point of view of both tonnage and value, being the starting material for Wittig reagents and catalyst ligands. The output in 1990 in Europe was ca. 2000 t. Products of comparable economic importance include the fire-retardant precursors tetrakis(hydroxymethyl)phosphonium chloride and sulfate.

The organophosphorus product with by far the largest sales value is still phosphonomethyl glycine (Glyphosate, Monsanto), at ca. 10^9 DM/a. Halogen-free phosphonic and phosphinic acid derivatives are of increasing importance in the production of nonflammable textiles. Approximately 1000 t/a of these products are produced.

The market for plastics additives (flame retardants, plasticizers and antioxidants) expressed as PCl_3 in the USA for 1990 is estimated at 30 000 t phosphorus trichloride, corresponding to

6800 t/a phosphorus. Of the total PCl_3 produced, 10 % (15 000 t/a) is converted to phosphorous acid for the production of industrial water-treatment additives. In Europe, the quantity of halogen-containing flameproofing agents based on esters of phosphoric acid was ca. 9000 t/a in 1990. Halogen-free products are estimated at 1500 t/a, and other organophosphorus plastics additives amounted to ca. 5000 t/a. In Japan in 1987, ca. 3600 t of phosphite esters, > 10 000 t halogen-free phosphate esters, and ca. 1400 t halogen-containing flameproofing agents were used. The total Japanese market for organophosphorus products was ca. 30 000 t, with a value of 180×10^9 Yen.

Apart from the esters of thiophosphoric acid used in plant protection, the most important compounds of this class are the zinc dithiophosphates used in lubricants, for which over 50 % of phosphorus pentasulfide production (ca. 65 000 t) was used in the United States in 1990. The quantity of phosphorus pentasulfide used in the production of flotation agents was < 2000 t/a. Production in developing countries with phosphate ore deposits is increasing. For example, in 1989 Chile consumed ca. 2400 t dithiophosphates, of which ca. 50 % was from its own production.

[Top of Page]

13. Toxicology

Thomas Hofmann

Phosphines. Tributylphosphine, a liquid with a garliclike odor, has an LD_{50} of 750 mg/kg in rats following oral administration, whereas the LD_{50} is slightly more than 2000 mg/kg in rabbits upon dermal application. The substance is irritating to the skin and mucous membranes. Inhalation causes nausea and, at higher concentrations, damage to the lungs and kidneys [139]. In rats, 4-h LC_{50} values of 0.17 and 12.5 mg/L have been reported for phenylphosphine and triphenylphosphine, respectively. Symptomatically, mild irritation of the respiratory tract was prominent [140]. Hyperemia, hypersensitivity to touch and sound, dermatitis, and anemia were observed in a 3–month inhalation toxicity study with phenylphosphine in rats and dogs [141]. The TLV-TWA value for phenylphosphine is 0.23 mg/m^3 [142]. For triphenylphosphine, the LD_{50} is 700 mg/kg in rats following oral administration, and in rabbits > 5000 mg/kg following dermal application [143]. It was not mutagenic in the Ames test [144].

Halophosphines. Halophosphines are corrosive to the skin due to their high reactivity with water. For dichloroethylphosphine, the lethal dose in mice following a 10-min inhalation is 1990 mg/m^3. For dichloro(2-fluoroethoxy)phosphine, it is 100 mg/m^3 in guinea pigs [145].

Phosphonium Compounds. Dodecyltriphenylphosphonium bromide possesses antimycotic properties and has been used in invert soaps. In higher concentrations, it is irritating to the skin [146].

Tetrakis(hydroxymethyl) phosphonium salts (chloride, sulfate, acetate/phosphate) are used to produce crease-resistant and flame-retardant finishes on cotton textiles and cellulosic fabrics. Tetrakis(hydroxymethyl)phosphonium chloride and tetrakis(hydroxymethyl)phosphonium sulfate were tested for carcinogenicity by oral administration in rats and mice and did not cause a dose-related increase in the incidence of tumors. However, male rats administered with the low dose level showed an increased incidence of leukemia, and an increased incidence of malignant lymphomas occurred in male mice of the low dose level. Tetrakis(hydroxymethyl) phosphonium chloride was negative in a two-stage skin initiation-promotion bioassay in mice. The mixed acetate/phosphate salt exhibited a weak promoting activity on mouse skin. Results of genotoxicity studies with these compounds were not consistent [147].

Phosphorous – Nitrogen Compounds. *N*,*N*-Bis (2-chloroethyl)tetrahydro-2*H*-1,3,2-oxazaphosphorin-2-amine 2-oxide monohydrate (cyclophosphamide) is used as a cytostatic agent in tumor therapy. In doses comparable to those given in clinical treatment, the compound causes an increased incidence of tumors in mice and rats and it is also genotoxic. Only in the organism is it metabolized to the active compound.

1,1′,1″-Phosphinylidenetris(2-methylaziridine) (METEPA) is used as a cross-linking agent in dye, textile, and polymer chemistry. The acute oral toxicity in rats (LD_{50}) is 136 mg/kg (male animals) and 213 mg/kg (female animals). TEPA (1,1′,1″-phosphinylidenetrisaziridine), which was formerly used as a flameproofing agent in the textile industry, found only limited application in the treatment of cancer, since the thio analogue was equally effective and had a lower toxicity. The LD_{50} in rats is 37 mg/kg following oral administration and 87 mg/kg upon dermal application [148]. Thio-TEPA (1,1′,1″-phosphinothioylidenetrisaziridine) is used as an antineoplastic agent. The LD_{50} in mice is 46 mg/kg following oral administration. The substance is genotoxic and leads to a higher incidence of malignant tumors in mice following intraperitoneal application and in rats following intraperitoneal or intravenous administration. Several cases of leukaemia have been reported in humans following treatment with Thio-TEPA [148], [178]. In contrast, hexamethylphosphoric triamide, which is used as solvent, catalyst, and stabilizer for polystyrene, is only slightly toxic after single dose administration (LD_{50}, oral: male rats, 2650 mg/kg; female rats, 3360 mg/kg). However, upon chronic inhalation, the substance caused a dose-dependent increase in the incidence of nasal tumors in rats. Moreover, pathological changes occurred in the entire respiratory tract [149-151]. In the United States the substance is classified as a suspected human carcinogen [142].

Phosphate Esters.
Trimethyl phosphate is metabolized to dimethyl phosphate in the body; the latter is excreted as a conjugate. The substance is only moderately toxic in acute doses (LD_{50} acute, oral, rat 2000 mg/kg). Hyperexcitability and tremor are prominent symptoms, and at higher doses death occurs due to cessation of respiration. Following repeated administration, flaccid and partly spastic paralysis of the extremities have been observed in rabbits [152]. In dogs, too, trimethyl phosphate is neurotoxic. The peripheral nerve fibers were found to be damaged [153]. Increased incidences of fibroma in male rats and increased incidences of endometrial tumors in female mice were observed after two years of oral administration of trimethyl phosphate to rats and mice for two years. Female rats and male mice showed no increased incidence of tumors [154]. Trimethyl phosphate was mutagenic in most test systems; however, high doses or concentrations were required in most cases [155-159], [179]. A sterilizing effect was found in mice, rats, and rabbits for trimethyl phosphate, whereby the target cells were the spermatozoa in the epididymis [160]. *Dimethyl phosphate*, a metabolite of trimethyl phosphate, shows no antifertility effects in male animals, in contrast to trimethyl phosphate. It has been found to be nongenotoxic in various test systems [170].

Triethyl phosphate, which is metabolized to diethyl phosphate and is excreted in the urine as such together with *S*-ethyl cysteine, has an LD_{50} (oral, rat) of 1310 – 1600 mg/kg. Poisoning is characterized by narcosis, excitability followed by CNS depression, loss of coordination, paresis of the hind extremities, disturbances in breathing, hypotonia, reduced cardiac activity, and reduced muscle tone. Triethyl phosphate is slightly irritating to the mucous membranes. Skin irritation and sensitizing effects have not been observed. The inhibition of choline esterases is low in comparison to other phosphate esters. Following repeated administration, triethyl phosphate causes an increase in the weight of the liver and adrenal glands with associated hepatocellular hypertrophy as the histological correlation. Triethyl phosphate is mutagenic in drosophila (recessive lethal test, eye mosaic assay). However, Ames test, cell transformation studies, in vivo cytogenic studies, and dominant lethal tests have given no indication of genotoxicity. The alkylating action is much weaker than that of trimethyl phosphate [161], [179].

Tributyl phosphate blocks cholinesterase only weakly [162]. The major metabolites are dibutyl hydrogenphosphate, butyl dihydrogenphosphate, and butyl bis(3-hydroxybutyl) phosphate [163]. The oral LD_{50} in rats is between 1390 and 3350 mg/kg. Upon subchronic oral administration of tributyl phosphate, damage to the liver, kidneys and urinary bladder were observed [180]. Tributyl phosphate was not neurotoxic in rats after acute or subchronic oral exposure [181]. Tributyl phosphate was administered via the diet to rats for two years. Dose levels were equivalent to 9, 33, and 143 mg/kg per day for males and to 12, 42, and 182 mg/kg per day for females. An increased incidence of urinary bladder hyperplasia and papillomas was observed at the high dose group in males and females. The incidence of transitional cell carcinomas of the urinary bladder was increased in males [182]. Mice were treated in the same way with dietary doses equivalent to 29, 169, and 585 mg/kg per day (males) and 24, 206, and 711 mg/kg per day (females). An increased incidence of hepatocellular adenomas was observed in males of the high dose group [183]. The mechanism of the bladder tumorigenesis in rats is probably nongenotoxic. High dietary doses of tributyl phosphate, given for 10 weeks, produced reversible urothelial cytotoxicity with regenerative hyperplasia. This cytotoxicity is likely due to a direct effect of tributyl phosphate or its metabolites rather than an indirect consequence of crystalluria [184]. Tributyl phosphate was not genotoxic in several test systems. It is not teratogenic in rats or rabbits and did not impair fertility in rats [180], [185]. Irritation of eyes and respiratory tract were observed after inhalation exposure in humans [180]. The TLV-TWA value is 2.5 mg/m^3 [142].

2-Ethylhexyl diphenyl phosphate has only a very low acute toxicity (LD_{50}, oral, rat and rabbit, > 24 000 mg/kg). No indications of carcinogenic effects were found in rats after two years of administration of the substance in the feed (up to 1 %) [164]. 2-Ethylhexyl diphenyl phosphate was not genotoxic in the Ames test, the HGPRT test, and the in vivo chromosome aberration test in rats. No teratogenic effects were observed in rats, and development of the offspring was only impaired at maternally toxic doses [186].

Tris(2-chloroethyl) Phosphate. The toxicological data of tris(2-chloroethyl) phosphate, which is used as a flameproofing agent, are summarized in [147], [187-189]. LD_{50} values of 390 – 1410 mg/kg (and > 2000 mg/kg in one study) have been reported for rats following oral administration. The substance is nonirritating to very mildly irritating to the skin and mucous membranes. It was not sensitizing to the skin in guinea pigs. Subchronic administration of tris(2-chloroethyl) phosphate caused increased liver weight in rats and mice. Additionally, rats showed increased kidney weights and degenerative changes in the hippocampus region of the brain. Results of mutagenicity studies on tris(2-chloroethyl) phosphate are not consistent, but the majority of tests were negative. Results of carcinogenicity studies suggest that tris(2-chloroethyl) phosphate possesses a weak tumorigenic activity, possibly via an epigenetic mechanism. When pregnant rats were treated with tris(2-chloroethyl) phosphate, toxic effects were found in the mother, but no fetotoxic or teratogenic effects were observed. Impairment of reproduction was observed in a two-generation study in mice.

Tris(2,3-dibromopropyl) phosphate, which was mainly used as a flameproofing agent in synthetic fibers for children's nightdresses, possesses only a low acute toxicity (LD_{50}, oral, rat: 5240 mg/kg) [147]. Renal inflammation and atrophy of the testicles were observed following subchronic dermal application in rabbits [166]. The compound was found to be genotoxic in several test systems [147], [167-169]. It was carcinogenic in mice and rats following chronic administration in the feed [147].

Aromatic Phosphate Esters.
Cresyl Phosphates. Among the aromatic phosphate esters, tricresyl phosphates with one or more *o*-cresyl groups are of toxicological importance. They give a completely different clinical picture following poisoning in human beings and some animal species than that resulting from alkyl phosphate poisoning. Motor paralysis, initially of the feet, tibia and thighs, and later of the hands and arms, occurs one to three weeks after intake. The initial flaccid paralysis progresses to a spastic condition. In the past, tricresyl phosphates have caused numerous mass poisoning incidents, for example, as softeners for PVC and in contaminated edible oils and machine-gun oil. The largest incidence of poisoning occurred in 1929/1930 in the United States following consumption of ginger spirit which was adulterated with tricresyl phosphate (“ginger paralysis”) [171]. In the organism, tricresyl phosphate is metabolized to the active agent by hydroxylation of the α-C atoms in the *ortho* position, followed by ring closure. The active agent irreversibly inhibits a nonspecific esterase in the CNS (neuropathy target esterase, formerly called neurotoxic esterase, NTE). Other compounds producing this type of neurotoxicity, which is known as organophosphate-induced delayed polyneuropathy (OPIDP) or neuropathy (OPIDN), are related phosphates, phosphonates, and phosphoramidates. Primarily, the axons are damaged. The demyelinisation of the affected nerves, which is later visible on histological examination, should be regarded as a secondary effect [172], [190]. Target organs after subchronic administration of tricresyl phosphate in rats and mice were adrenals, kidneys, ovaries, and testes. Reduced grip strength occurred in mice. Tricresyl phosphate was not carcinogenic in rats and mice. It was not mutagenic in the Ames test and did

not induce chromosomal aberrations or sister chromatid exchanges [191]. Tri-*o*-cresyl phosphate was not teratogenic in rats [192]. It caused a dose-dependent decrease in sperm motility and sperm population in the epididymis in male rats [173], [174]. The TLV-TWA value has been set at 0.1 mg/m^3 [142].

Triphenyl phosphate itself is not neurotoxic. The effects of this type that are occasionally observed are attributed to impurities [190], [193]. Triphenyl phsophate has a low acute oral and dermal toxicity and is not irritating to the skin. Likewise, repeat-dose studies showed low toxicity. It did not affect reproduction when administered to rats during gametogenesis, through mating and gestation. No teratogenic effects were seen. Triphenyl phosphate was not genotoxic in several test systems [194]. The TLV-TWA value for triphenyl phosphate is 3 mg/m^3 [142].

Phosphites. Due to its tendency to hydrolyze, *trimethyl phosphite* is irritating to the skin, eyes, and respiratory tract. Studies on the acute oral toxicity gave LD_{50} values of 1600 – 2890 mg/kg in rats. Following single administration of high doses (in the LD_{50} range), flaccid paralysis of the extremities was observed. Local irritating properties of the substance are prominent when the substance is inhaled repeatedly. After repeated oral administration to rats, changes of the lungs, fatty degeneration of the liver, and reduced sperm production were observed. The results of mutagenicity tests are not consistent. Upon oral administration to pregnant rats, trimethyl phosphite causes an increase in fetal resorption rate as well as anomalies in the offspring [170]. The TLA-TWA value has been set at 10 mg/m^3 [142]. *Diethyl phosphite* (oral LD_{50} in rats 3500 – 5560 mg/kg) and *triethyl phosphite* (oral LD_{50} in rats 1840 – 4000 mg/kg) are mildly irritating to the skin in rabbits and induced skin sensitization in guinea pigs. These compounds were not mutagenic in the Ames test and micronucleus test. Lung damage was observed after repeated oral administration of diethyl phosphite [195], [196]. The following LD_{50} values have been reported for other aliphatic phosphites following oral administration to rats: dimethyl phosphite, 3800 mg/kg; tri-*n*-butyl phosphite, 3200 mg/kg; triisooctyl phosphite, 19 200 mg/kg [175].

The minimum lethal dose in rats following subcutaneous administration is ca. 2400 mg/kg for triphenyl phosphite, 3400 mg/kg for tri-*p*-cresyl phosphite, 3400 – 5700 mg/kg for tri-*m*-cresyl phosphite, and 11 300 mg/kg for tri-*o*-cresyl phosphite. Poisoning was characterized initially by mild, and then severe tremors, normally of the larger muscle groups. Hyperexcitability, spasticity, ataxia, and flaccid paresis of the extremities appear several days after administration. Tri-*o*-cresyl phosphite and triphenyl phosphite exhibited the highest activity. Upon oral administration to chickens, tri-*o*-cresyl phosphite causes neurotoxic effects similar to tri-*o*-cresyl phosphate. Probably, it is oxidized to the latter in the body [176]. In the case of triphenyl phosphite, which causes ataxia in rats, chickens, and cats, the pattern of injury caused differs from that described for the tricresyl phosphates [197].
